PREFACE

This is Volume I of a *Handbook of Mineral Dressing*. As such it deals with the processes, largely mechanical, involved in the concentration of metalliferous ores and the beneficiation of industrial minerals. Volume II is planned to treat of the preparation of fuels and of the methods, mostly chemical, by which metalliferous and nonmetallic concentrates are rendered into primary-consumer products. The two volumes are planned thus to constitute a compendium of the arts by means of which the mineral crust of the earth is converted into the forms that are utilized by manufacturers and, in some cases, by ultimate consumers.

The predecessor volume, *Handbook of Ore Dressing*, suffered the usual fate of technical handbooks. It appeared at the beginning of several revolutionary changes in practice, *e.g.*, the general adoption of the cone-type crusher; the substitution of subaeration and matless flotation cells for agitation-froth and mat-type machines; and the almost universal change-over to soluble collectors in floating sulphide ores. Hence it was out of date in important particulars almost as soon as it appeared. Possibly—probably—the present volume will meet the same fate. Perhaps that is what the engineer should wish for, since it is a concomitant of progress.

Revision has involved complete or substantial rewriting of somewhat more than half of the first edition, comprising the sections on Metallic Minerals, Grinding, Flotation, and Sampling and Testing. Upward of 30 to 50 per cent. of the material of the sections on Crushing, Screening, Washing, Gravity Concentration, Electrical Concentration, Miscellaneous Methods of Concentration, and Storage and Transport of Materials has been rewritten. New sections have been added dealing with Industrial Minerals, Cement, Dust Collection and Air Sizing, and Dry Grinding. The remaining technical sections have been revised sufficiently to bring them up to date. The general sections, with the exception of that on Mathematics, have been omitted in view of the publication of the *Handbook of Engineering Fundamentals*, by O. W. Eshbach.

The general plan of presentation is the same as was followed in the predecessor volume, with the theme carried in larger type, and supplementary text, examples, operating data, and the like in small type. References, printed in italics in the running text, are in the form adopted in legal writing, with volume number, abbreviation of the periodical, and page number set down in the named order. Table 48, Sec. 22, gives the interpretations of the reference abbreviations in those cases where these are not apparent on the face.

In engineering, practice is the best index of expectable performance. Established laws enable the informed scientist to predict with reasonable accuracy what will occur in a physical system that can be defined completely. But such systems are, of necessity, simple. Technical operations, even the least complex, involve numerous components and conditions that are not only indefinable but are frequently not even recognized as present. Under such circumstances prediction is possible only by study of similar technology, in which there are present essential controlling conditions that parallel those in the case in question. It is the function of an engineering handbook to record such illustrative practices and to point out what appear to be the controlling conditions. It is the task of the editors to make such selection from the mass of data available that reasonably representative coverage is effected; to be fairly critical to the end that experiment unverified by field performance is not given the same weight as established tonnage-producing operation, nor is record of such experiment denied a place because it runs counter to personal predilection; to have the courage both to hazard new generalization when conditions seem to warrant such action, and to criticize generally accepted practice if such action seems indicated. These are the principles which underlie the present volume.

Costs as given in the text are specifically dated or the date indicated by the context. They may usually be related to present time by a multiplier representing the ratio of combined labor and commodity index figures for the published date and the present.

The editor records with regret the deaths, since publication of the earlier work, of four of his associate editors: Frederick E. Beach, John M. Callow, R. C. Canby, and Percey F. Smith. Mr. Callow's death occurred after he had completed the revision of his manuscript for the present volume.

Much of the source material for the flowsheets in Section 2 and for many of the operating data in the other sections was in the form of answers to elaborate questionnaires sent out by the editor and graciously filled in and returned by busy men in the field. Acknowledgment has been made by name in Section 2 wherever possible. But the editor wishes here to express thanks not only to those named but to the many not named who, through formal questionnaires, through letters, as courteous guides in their mills, in conversations in divers places, and by publication in the technical press, have made their experiences available and thereby made this book possible. No one who has not tried to write a technical handbook, or a part thereof, realizes how little he or any other one person knows about the subject that he considers his specialty. Hence this work is dedicated

To My Colleagues Everywhere

In Appreciation

Of Their Generous Help

TABLE OF CONTENTS

SECTION 1

INTRODUCTION

Mineral dressing is the art of treating the crude crust of the earth to produce therefrom the primary-consumer derivatives. The essential operation in all such processes is separation of one or more valuable desired constituents of the crude from the undesired contaminants with which it occurs associated. Mineral dressing has three principal branches, *viz.:* ORE DRESSING, which comprises the methods of separation of solid inorganic crudes by means which do not effect substantial chemical change; EXTRACTIVE METALLURGY, which utilizes chemical reaction for separation of the constituents of solid inorganic crudes; and FUEL TECHNOLOGY, which employs both physical and chemical methods for separation and rearrangement of liquid and solid carbonaceous crudes. The magnitude and expanse of the art may be judged by reference to Fig. 1, this section, and Figs. 6 and 7, Sec. 2.

Mineral dressing is to be looked upon primarily as a manufacturing process for which the raw material is the crude, and the finished product is that derivative thereof which best supplies the demand of the primary consumer. From such a viewpoint a plant manager should be conversant equally with the technology of production, the product potentialities of his crude, the geographical distribution of his markets, their demand potentialities, the specifications prevailing, and the expectable trend of prices. This means that, as of the past, he should know the ultimate uses of present and potential products, the ability of the markets to absorb new production, the possibility and availability of substitutes, production and price histories, and the economic significance of quality. As of the late thirties, in the United States, however, the demands imposed on executive time by bureaucratic inquisition, and in bargaining with labor, were so great that study of even broad questions of technical policy were, of necessity, largely delegated, primary markets only could be followed, and expansion lagged not only from nonrecognition of possibilities, but also from lack of incentive to search for them.

Definitions. A CRUDE is any mixture of minerals in the form in which it occurs as a part of the earth's crust. An ORE is a solid crude containing a valuable constituent in such amounts as to constitute a promise of possible profit in extraction, treatment, and sale. The valuable constituent of an ore is ordinarily called VALUABLE MINERAL, or often just MINERAL; the associated worthless material is called GANGUE. In some ores the mineral is in the chemical state in which it is desired by primary consumers, *e.g.*, graphite, sulphur, asbestos, talc, garnet; in fact this is true of the majority of nonmetallic minerals; in metallic ores, however, the valuable mineral is rarely the product desired by the consumer, and chemical treatment of such mineral is a necessary step in the process of beneficiation. In such cases the sales product is usually the result of concentration by the methods of ore dressing, followed by further concentration by the chemical methods of metallurgy. The valuable product of the ore-dressing treatment is called CONCENTRATE; the discarded waste is TAILING.

Concentrate is, in most cases, the feed to the metallurgical plant. If the metallurgical process is one in which separation is effected in a melt, the process is called SMELTING; if the separation is effected by differential or selective solution, the process is LEACHING or LIXIVIATION; where the process is one of selective vaporization, it is called RETORTING. The valuable metal product of smelting is usually differently named according to the metal involved, *e.g.*, BLISTER (copper), BASE BULLION (lead), PIG (iron), etc.; the waste is SLAG.

The crudes of fuel technology are RAW COAL and CRUDE PETROLEUM; treated coal is CLEANED COAL, and the reject is SLATE or ROCK. The primary derivatives of crude petroleum are the familiar natural and refinery gases, gasolines, kerosene, the various fuels of increasing gravity, down to coke, and refinery asphalts, pitches, and the like. There is, in general, no reject or tailing, barring occasional unsalable coke and the gas flares and nightly burned residuum of the hot-oil plants.

Fundamental operations of mineral dressing are SEVERANCE, or breaking apart of the associated minerals or constituents of the crude, and SEPARATION of the severed con-

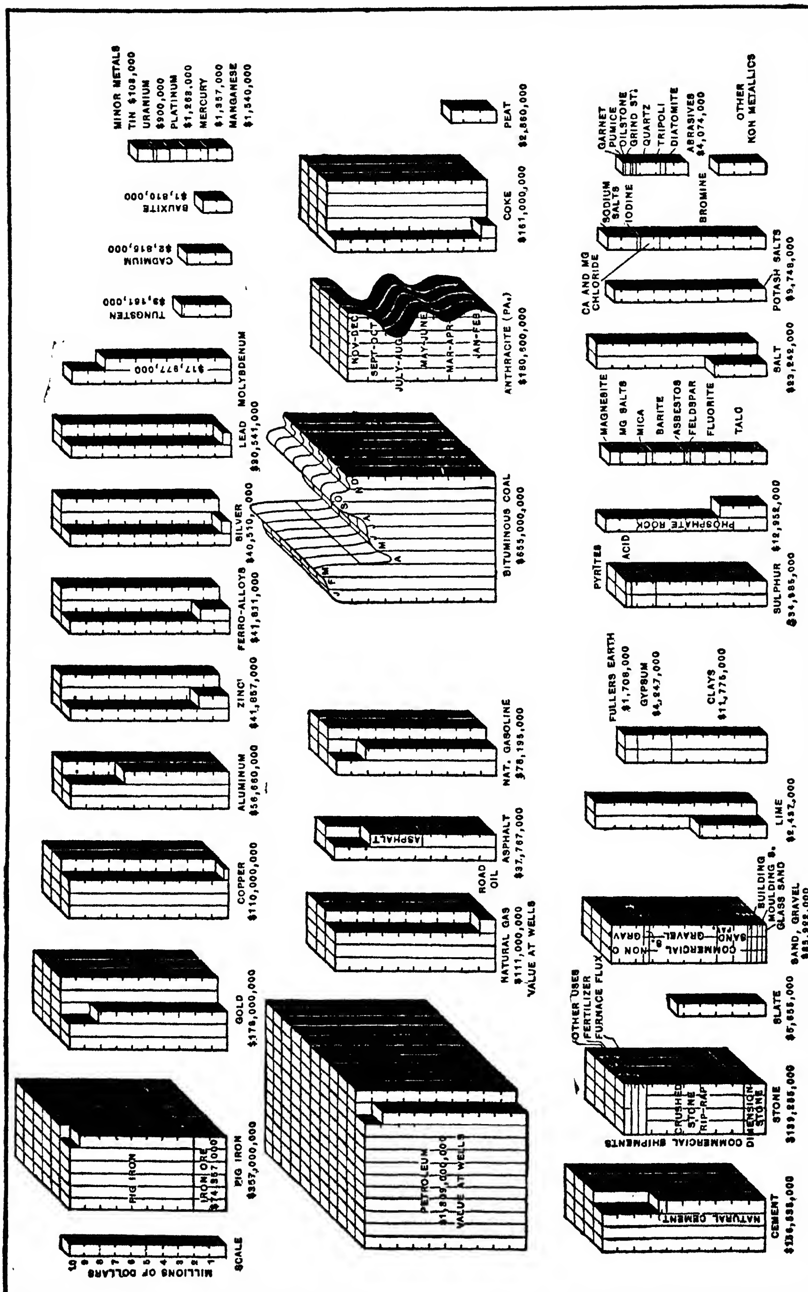

FIG. 1. Mineral production of the United States in 1938 (*after Raisz, 22 MMt 159*).

stituents, which normally involves causing them to take different paths through a given apparatus. The processes differ according to the means required or used to effect these two ends.

Severance. The means differ according to the crude. With solid crudes, which are to be separated without essential chemical change, the almost universal method is some form of breaking or comminution. Chemical severance with solids usually involves either dissolution in aqueous solutions or decompositions of the oxidation-reduction type at high temperatures, with or without a selective phase change. Severance of petroleum crudes invariably involves selective phase changes, which may be accompanied by more or less profound chemical reaction.

Separation methods are much more diversified than those of severance. In ore dressing they are based upon utilization of some property in which the intermingled severed minerals differ either in kind or degree, to effect a differential response to some impulsive force. Thus magnetite, which is highly permeable to magnetic forces, moves readily toward a field of concentrated magnetic force which has no appreciable effect on the motion of a quartz grain similarly exposed; galena, with a specific gravity of 7.5, sinks under the influence of gravity in a fluid medium in which quartz (sp. gr. 2.6) rises; or again galena, by reason of the contained lead ion, may be caused to attach air bubbles to its surface in sufficient volume to cause it to float in water, while quartz, lacking the essential lead ion, does not attach air bubbles under the same conditions, and sinks. In metallurgy differences in the specific gravities or in the mobilities of the phases into which the constituents have been changed in the process of severance are made use of to produce differential movement; thus gold dissolved in certain aqueous solutions is drained away from solid gangue; liquid slag floats on molten iron in the blast furnace and the two are drawn off through separate ports; sulphur combined with oxygen in gaseous phase flows away from a solid metal-bearing residue in zinc roasters, copper reverberatories, and lead blast furnaces. In petroleum refining, vaporized low-boiling products flow away from higher-boiling fractions which are liquid under the same conditions of temperature and pressure.

The technological practice of mineral dressing involves both the design of plants and their operation. The former involves decision as to location, capacity, character of finished product, and type of flowsheet; the latter, with the details of performance and the techniques involved in their control.

Location of a mineral-dressing plant involves a balance between the source or sources of crude, the point or points of consumption, the amount of bulk concentration effected in treatment, the sources and quantities of power, water, and supplies, the labor market, the facilities for disposal of waste, transportation facilities and rates, etc. Ore-dressing plants are usually located at or near the mine, because they normally serve only one source of crude, beneficiation usually involves a relatively high degree of concentration, and transportation becomes a prevailing element of cost. The reverse is normally true in petroleum refining; the bulk of refined products is not substantially less than that of the crude, the principal markets are at the centers of population rather than at the centers of production, and transportation charges per unit of weight (or volume) are materially lower for crude than for finished products. Furthermore, sources of supply are relatively scattered by comparison with those for solid crudes. Hence Midcontinent and South and East Texas crudes are refined in Chicago and on the Atlantic seaboard, while Pennsylvania lubricating-oil crudes are refined near the wells, and the small bulk of lubricating-oil concentrate is shipped countrywide, the lighter products being sold locally. The smelter requires supplies, primarily fuel and fluxes, which may bulk as large as the concentrate feed or larger; the tendency is, therefore, to locate the smelter nearer and nearer to the source of fuel, or to the points of metal consumption, the more scattered the sources of metallic-concentrate supply. Thus tin concentrates from Malay and from Bolivia were shipped to England; Australian zinc concentrate went formerly to Belgium and now goes to the United States; African copper concentrate has been shipped to U. S. Atlantic seaboard; Lake Superior iron ore goes to Cleveland and Pittsburg, etc. On the other hand, with an exceptionally large source of feed, the smelter tends to go to the source; thus there is a smelter at Garfield, Utah, 1 to 2 mi. from its principal supplier, the UTAH COPPER mills; one at Miami, near MIAMI COPPER Co. and INSPIRATION; one at CHINO, one at RAY, one at ANACONDA, and one at McGill (NEVADA CONSOLIDATED).

Capacity of a mineral-dressing plant depends upon the potential yield of the source of supply, the size and character of the market, the competitive position, and the funds available. The incidence of the various factors approaches the obvious, although the details of incidence are infinitely varied. The best plant is one comprised of parallel units of such capacity that at least one may be kept going at full efficient rate in times of minimum market demand, and others can be thrown in, one at a time, as demand increases.

When processes are not necessarily continuous from start to finish, as, for example, is the case as between crushing and subsequent treatment in ore-dressing and hydrometallurgical plants, or topping and cracking in oil refineries, the economic advantages of large units in the preliminary treatment may be retained by providing storage between these and later processing units, and operating the large-capacity units on a part-time schedule.

Analyses of most profitable exhaustion rates under conditions of a free economy and uncontrolled interest rates have been made (see Hoover, *Principles of mining*, McGraw-Hill, 1909). Under the conditions postulated they are helpful in deciding plant capacity for plants serving a known, limited source of crude. Under modern conditions they are worse than useless, except as a tool of the politically omniscient.

Character of finished product is determined by co-consideration of the character of the crude and of the dressing processes available, and variations in marketability with quality. If metalliferous products are to be shipped long distances at high freight rates, ore dressing must aim at maximum elimination of every substance physically rejectable (including water); on the other hand the impurities in blister copper, low-grade lead bullion, and the like weigh so little that no economy would result from refining them before shipment, under conditions that penalized the process otherwise. In the face of high freight and smelter charges it will frequently pay to run arsenical gold concentrate down to bullion by roasting and cyanidation; on the other hand, when iron is desired as flux and the distance from the smelter is not too great, it will usually pay to make, say, a low-grade copper concentrate in which the bulk of the diluent is iron and sulphur. Premium gasolines will usually pay better than straight-run in a refinery near a large city even though a certain amount of straight-run is decomposed and degraded in reforming, but at the field topping off straight-run is usually economical.

A contrary situation arises in the case of Lake iron ores, most coal shipments, and certain limes, crushed stones, building sands, and the like, which are sold on the basis of specifications that fix certain minimum requirements as to purity, but give no bonuses for greater purity. Under such circumstances all weight dressed out in excess of that needed to make specification represents loss of material salable at full price. Obvious methods of avoiding such loss, going to the extent of mixing back tailing, are common practice.

Type of flowsheet to be provided depends upon the characteristics of the crude and the decisions that have been made as to location, capacity, and grade of product. The essential elements of the flowsheet must be such as take advantage of the differences in physical and/or chemical properties of the constituents of the crude; the details will vary according to the rule that, in general, high recovery of a low-grade product and low recovery of a high-grade product are equally easy and cheap to attain; and that high recovery of a high-grade product verges on prohibitive expense, approaching that barrier more or less closely according to the degree of technologic advance that has been made in the particular field. Thus copper can be run down to 0.04% or less in tailing or up to 40 to 45% in concentrate in a chalcocite ore without extreme expense, but to run a copper tailing down to 0.04 oz. per ton, which grade is relatively easy to attain with a gold ore, or to run a gold concentrate up to 40 to 45% would, even if possible, raise expenses to a prohibitive figure. Similarly 100-octane aviation gasoline produced by alkylation is profitable when the yield on original crude is low, but to attempt to produce it on a high-yield basis with present-day processes would be financial suicide.

SECTION 2

METALLIC MINERALS

USES, ORES, PRODUCTION, TREATMENT SCHEMES, SELLING

1. INTRODUCTION

Metals occur in ores either in the native state (*e.g.*, Au, Ag, Pt, Cu) or as salts or oxides (CuS, Fe_2O_3, $PbCO_3$, etc.). But no matter what the chemical form, the metal or metallic mineral is invariably associated with more or less—usually more—barren rock. The form in which the metal is required by the primary consumers is as relatively pure substance. Hence a more or less extended campaign of purification, usually involving, in order, ore dressing, metallurgical extraction, and chemical refining, intervenes between delivery of ore at the mine exit and delivery of the metal to the purchaser.

This section presents selected records of ore-dressing methods as practiced in operating plants. These methods are grouped according to the principal metal or metals sought, and are presented, in general, in the form of annotated flowsheets. Subsequent treatment of concentrate is indicated briefly. Data as to uses of the metal and production statistics are given; price histories and selling methods are summarized in Art. 50.

Selection of an ore-dressing treatment scheme that is the best available, or a close approximation thereto, is an essential step in profitable exploitation of a given ore deposit. In order to effect such a selection it is necessary to know what methods of concentration are applicable, what their performance limitations are, and what it costs to operate them. Flowsheets give such information, if properly analyzed. But the bases upon which selection of a flowsheet depends are not solely technical, *i.e.*, the flowsheet selected is not necessarily the one that yields maximum recovery of high-grade concentrate. MAGMA COPPER Co. (Fig. 16) makes a concentrate assaying 13% Cu when 30% Cu is possible, because the smelter is at the plant and freight on concentrate is not an expense, and further because the pyrite left in the concentrate is an asset at a smelter receiving siliceous gold ores. ANACONDA makes a similar low-grade pyritic concentrate because again the smelter is at the mill and sulphuric acid is wanted in other processes in the plant. On the other hand, MOUNT ISA, shipping zinc concentrate 10,000 mi., runs the grade up to 53% on a high-iron

sphalerite despite high tailing loss, in order to save freight. Consequently, in studying flowsheets, all pertinent factors should be considered, else the records will present a picture of bewildering and apparently senseless difference and complexity.

2. FLOWSHEETS

The plant for separating metalliferous mineral from gangue is called a CONCENTRATOR, or, less definitively, a MILL, and the process is CONCENTRATION or MILLING. A mill flowsheet is an economic compromise, within the limits of technical possibility, between the market schedule for concentrate and the cost of concentration. Smelter schedules, either by definite specification or, in conjunction with transportation tariffs, by economic penalties, usually impose a minimum grade of concentrate; while smelter bonuses and the economic advantage that lies in reduction of the tonnage transported offer reward for increase in concentrate grade. At the other end of the scale, the lithological character of the ore imposes more or less definite and controlling limitations on the method of concentration available and, thereby, correlatively on grade of concentrate, recovery, and cost.

Principles. There are, perhaps, half a dozen generalizations applicable to the technology of concentrating plants, which are of such universal incidence that failure to find them followed in any given flowsheet should immediately raise questions as to the suitability of the flowsheet or as to the considerations other than technical that have prevailed in the design. These generalizations follow:

(1) Concentrate and/or tailing should be taken out of the mill stream at as coarse a size as is consonant with maintenance of the desired grades of concentrate. Tailing taken out at coarse sizes should be credited with the cost of further size reduction and (usually) with the increase in cost of concentration at fine as opposed to coarse sizes. When concentrate is taken out at coarse size, recovery with respect to the contained mineral will be higher than if separation is deferred, for the reason that comminution of valuable mineral invariably produces some very fine particles that are extremely difficult to save.

(2) Concentrating processes other than flotation all depend upon the existence of an appreciable difference in some physical property of valuable mineral and gangue, *e.g.*, size, hardness, specific gravity, permeability, appearance, etc. If no such difference exists, flotation, which depends upon chemical rather than physical differences, must, perforce, be used, if concentration is to be effected by physical means.

(3) Concentration by physical means can, in general, be performed at any size at which the constituent minerals are sufficiently severed to justify designation of individual pieces as concentrate and/or tailing. Flotation normally requires comminution to at least 35- or 48-m.

(4) Time is an essential factor in all concentrating operations. In general the amount of time required per unit of weight for separation increases markedly with decrease in size of particle. It follows that the capacity of a concentrating machine or operation increases with increase in size of the feed particles.

(5) The cost of any concentrating operation involving either special preparation of feed or special handling of products should be charged with the cost of these special accessories.

(6) If, as is usually the case, maximum profit is the aim of a concentrating operation, this end is normally served best by some combination of recovery and grade of concentrate that does not include the technical maximum of either quantity.

(7) All other things being equal, a large unit, be it a crusher or a grinding mill, a concentrating machine, or some piece of accessory apparatus, will do its appointed job more efficiently and more cheaply than a small unit, provided only that it is equally well designed and that it is kept working at or near full capacity.

There are, similarly, a small number of economic facts and principles, common to industries generally, and not specific to concentration, which should, nevertheless, be ever in the mind of the student and the designer of flowsheets. Perhaps the one most commonly ignored is that listed first below:

(1) The most efficient plant possible cannot make money unless there is ore to work on, and a sufficient quantity to permit work to continue long enough to allow amortization of plant and equipment at a reasonable percentage rate.

(2) Estimates both as to production cost and selling price may be made with much more assurance for the common metals than for the rare metals. Neither demand for nor supply of the former will change to the same extent or with the same percentage rapidity as is possible with the latter.

(3) If the margin between selling price and production cost is small, it is foolhardy to build a plant on the basis of assumptions either as to price improvement or cost reduction. This is especially true when the technology of production is well established and the cost already relatively low. In this connection it should be borne in mind that an increase in

[Text continued on p. 6.]

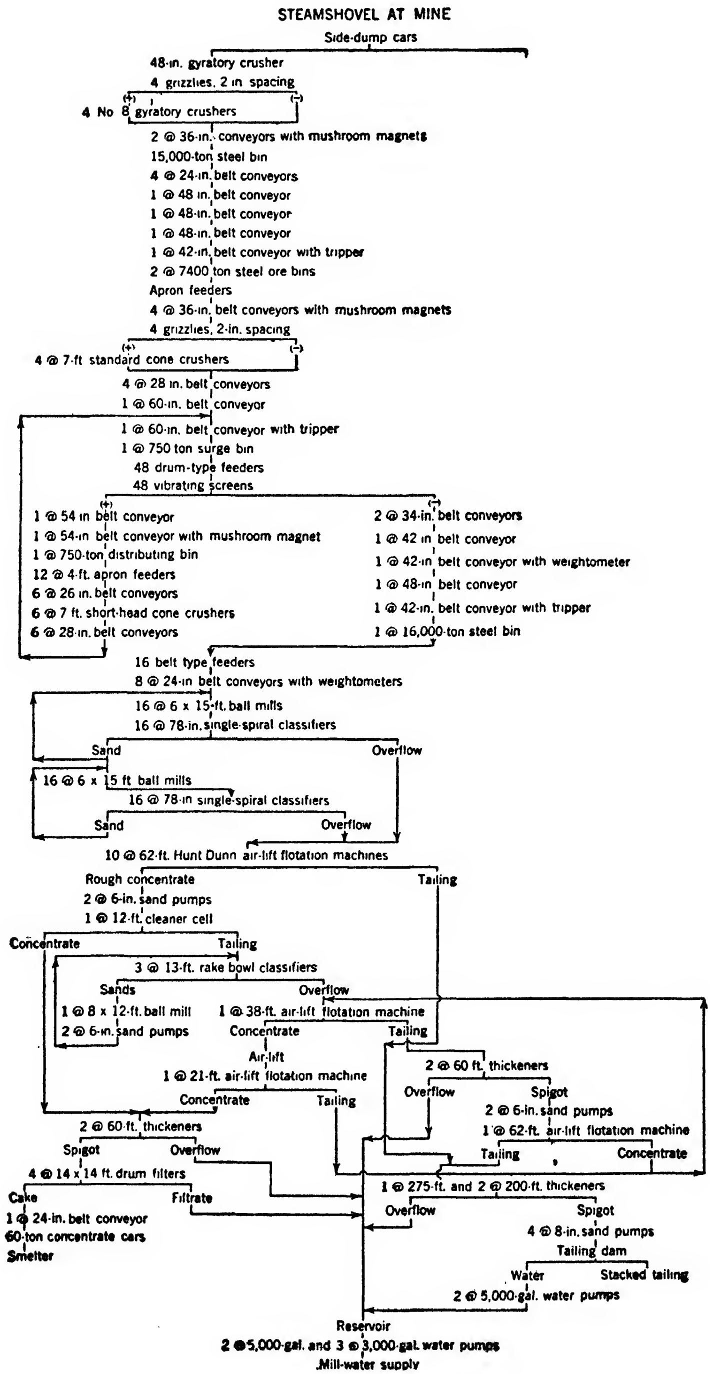

FIG. 1. Line form of flowsheet.

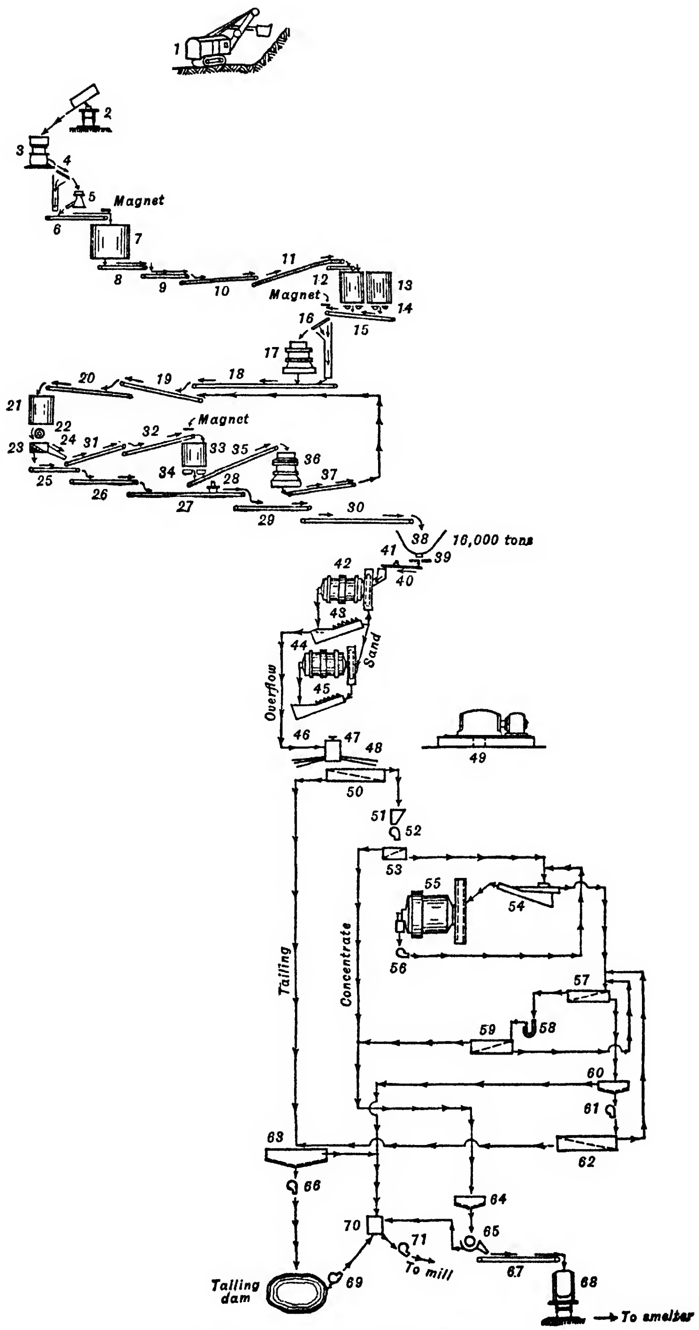

FIG. 2. Pictorial form of flowsheet.

Legend for Fig. 2:

1. Full-revolving electric shovel, 4 1/2-yd. dipper.
2. 20 and 30-yd. side-dumping cars, standard-gage track.
3. One 48-in. gyratory crusher. Driven by 200-hp. motor through belt drive to pinion.
4. Four grizzlies. 70-lb. rails spaced 2-in. spaces.
5. Four No. 8 Gates gyratory crushers. Driven by 75-hp. motors through Texrope to pinion.
6. Two conveyors. No. 1A and 1B, 36-in. belt, 1130 ft. long, 290 ft. per min. Lift 51 ft. Driven by 75-hp. motor through speed reducer. Belt-propelled, clutch-type, tripper car. Over bin. Each conveyor has magnet.
7. One 15,000-ton steel ore bin. With manganese-steel gates on bottom to discharge into tripper cars.
8. Four conveyors, Nos. 2E, F, G, H, 24-in. belt, 225 ft. long, speed 450 ft. per min. Driven by 10-hp. motor through speed reducer. Self-propelled reversible tripper cars. Belt independent of tripper. Tripper feeds belt from floor of bin above.
9. One conveyor, No. C4, 48-in. belt, 415 ft. long, 450 ft. per minute. Driven by 100-hp. motor through gear and pinion reduction. Fed by 16.
10. One conveyor, No. C5, 48-in. belt, 418 ft. long, 440 ft. per min. Lift 46 ft. Fed by 17. Driven by 100-hp. motor through gear and pinion reduction.
11. One conveyor, No. C6, 48-in. belt, 480 ft. long, 440 ft. per min. Lift 54 ft. 0 in. Fed by 18. Driven by 100-hp. motor through gear and pinion reduction.
12. One No. 3A conveyor, 42-in. belt, 314 ft. long, 450 ft. per min. Driven by 30-hp. motor through gear and pinion reduction. Self-propelled and reversible tripper car. Conveyor over bin.
13. Two 7400-ton steel ore bins. Sliding gates feeding into apron feeders.
14. Four units of four 4-ft. 0-in. manganese-steel apron feeders. Driven from pulley on conveyor pulley through gear and pinion reduction. Speed 12 ft. per minute.
15. Four belts, No. 4, 36-in. belt. 170 ft. long, 272 ft. per min. 10-ft. lift. Driven by 10-hp. motor through gear and pinion reduction. Each belt has magnet over grizzlies.
16. Four grizzlies. Bars 2-in. spaces.
17. Four 7-ft. 0-in. standard cones. Driven by 300-hp., synchronous motors, direct connected.
18. Four conveyors. 28-in. belts, 355 ft. 0 in. long, 400 ft. per min. Lift 18 ft. 0 in. Driven by 20-hp. motor through speed reducer.
19. One conveyor, No. 5A, 60-in. belt, 632 ft. long, 650 ft. 0 in. per min. Lift 30 ft. 0 in. Driven by 200-hp. motor through speed reducer.
20. One conveyor, No. 5B, 60-in. belt, 717 ft. long, 650 ft. per min. Lift 26 ft. 0 in. Driven by 200-hp. motor through speed reducer. Self-propelled reversible tripper car over screen-feed bins
21. One 750-ton steel bin for screen feed.
22. Forty-eight drum feeders to screens. 18-in. dia. and 46 in. long.
23. Forty-eight electric vibrating screens.
24. Twenty-four screen oversize-discharge chutes.
25. Two conveyors, No. 8A1, No. 8A2, 34-in. belts, 228 ft. 0 in. long, 440 ft. per min. Feed from screens. Driven by 25-hp. motor through gear and pinion reduction.
26. One conveyor, No. 8B, 42-in. belt, 158 ft long, speed 420 ft. per min. Driven by 15-hp. motor through gear and pinion reduction.
27. One conveyor, No. 8, 42-in. belt, 521 ft. long, speed 470 ft. per minute. Lift 58 ft. 0 in. Driven by 100-hp. motor through gear and pinion reduction.
28. One weightometer.
29. One conveyor, No. 9, 48-in. belt, 820 ft. long, speed 490 ft. per min. Driven by 250-hp. motor through gear and pinion reduction. Lift 100 ft. 9 in.
30. One conveyor, No. 10, 42-in. belt, 1,347 ft. long, speed 450 ft. per min. Driven by 100-hp. motor through gear and pinion reduction. Self-propelled reversible tripper car over 16,000-ton bin. Lift 39 ft. 0 in.
31. One conveyor, No. 5C, 54-in. belt, 658 ft. 0 in. long, speed 570 ft. per min. Lift 30 ft. 0 in. Driven by 150-hp. motor through gear and pinion reduction.
32. One conveyor, No. 5D, 54-in. belt, 717 ft. 0 in. long, speed 570 ft. per min. Lift 26 ft. 0 in. Driven by 150-hp. motor through gear and pinion reduction. Self-propelled reversible tripper car. Has magnet before entering tripper car.
33. One 750-ton steel ore bin. Feeds 7-ft. short-head cones.
34. Six units, two per unit, 4-ft. 0-in. apron feeders. Manganese steel. Each unit driven by 15-hp. motor through right-angled drive-speed reducer, thence through gear and pinion reduction.
35. Six conveyors, No. 6A, 26-in. belt, 80 ft. 0 in. long, speed 540 ft. per min. Driven direct by 10-hp. geared motor.
36. Six 7-ft. short-head cones. Driven by 250-hp synchronous motors through pulleys and Texrope drive.
37. Six conveyors, No. 7, 28-in. belt, 150 ft. long, speed 480 ft. per min. Lift 16 ft. 0 in. Driven by 20-hp. motor through speed reducer.
38. One 16,000-ton mill ore bin. Suspended type.
39. Sixteen feeders, conveyor. 42-in. belts, 54 ft. long, speed 32 ft. per min. Driven by 2-hp. motor through reducer.
40. Eight conveyors, No. 11, 24-in. belt, 92 ft. long, speed 150 ft per min., lift 9 ft. 0 in. Driven by 5-hp. motor through gear and pinion reduction.
41. Eight weightometers.
42. Sixteen 6 by 15-ft. primary ball mills. Driven by 300-hp. synchronous motors. Magnetic clutch. Speed of mills, 23.1 r.p.m. Two mills per unit.
43. Sixteen 78-in. single spiral classifiers. Driven at 3 1/2 r.p.m. by 7 1/2-hp. MotoReducers.

Legend for Fig. 2—Continued:

44. Sixteen 6 by 15-ft. secondary ball mills. Driven by 300-hp. synchronous motors. Magnetic clutch. Speed of mills, 23.1 r.p.m. Two mills per unit.

45. Sixteen 78-in. single spiral classifiers. Driven at 3 1/2 r.p.m. by 7 1/2-hp. MotoReducers.

46. Eight main 12-in. headers, from primary and secondary classifier overflow. One mill per unit.

47. Two pulp distributors to flotation machines.

48. Ten launders; five launders from each pulp distributor to flotation machines.

49. (Air production. All air at 2-lb. pressure.)

Two 20,000-cu. ft. per min. centrifugal blowers. Driven direct by 650-hp. synchronous motors at 3600 r.p.m.

One 30,000-cu. ft. per min. centrifugal blower. Driven direct by 650-hp. synchronous motor at 3600 r.p.m.

Two No. 8 cycloidal blowers, 8000 cu. ft. per min. each. Driven by 200-hp. motors through belt and pulleys.

50. Ten 62-ft. 0-in. Hunt-Dunn type flotation machines.

51. One sump.

52. Two 6-in. sand pumps.

53. One 12-ft. Hunt type re-treatment cell.

54. Three 13-ft. 0-in. bowl-type classifiers. Speed bowl rakes 6 r.p.m. Sand rakes 18 s.p.m.

55. One 8 by 12-ft. ball mill. Regrind, 12 r.p.m. Driven by 300-hp. synchronous motor.

56. Two 6-in. sand pumps.

57. One 38-ft. 0-in. Hunt-Dunn type flotation cell.

58. One air lift, 25-lb. pressure.

59. One 21-ft. Hunt-Dunn type flotation cell.

60. Two 60-ft. thickeners.

61. Two 6-in. sand pumps.

62. One 62-ft. 0-in. Hunt-Dunn scavenger flotation cell.

63. One 275-ft. slime traction thickener. Two 200-ft. slime traction thickeners.

64. Two 60-ft. thickeners.

65. Four 14 by 14-ft. drum-type filters. Two 8-ft. 6-in. 7-disk filters.

66. Four 8-in. sand pumps.

67. One conveyor, No. 12, 24-in. belt, 744 ft. long, belt speed 110 ft. per min. Drop 11 ft. 0 in. Driven by 7 1/2-hp. motor through reducer.

68. 60-ton concentrate cars to smelter.

69. Two 5000-gal. per min. fresh-water pumps. Direct driven by 250-hp. induction motor.

70. One reservoir, receiving all reclaimed water.

71. Five return-water pumps: two 5000 gal. per min.; three 3000 gal. per minute.

the price of any particular metal improves the competitive position of substitute metals and alloys; that price no longer fluctuates freely in response to demand; that profits are taboo; and that future profits estimated on the basis of a rise in selling price are, probably, in the chimerical class.

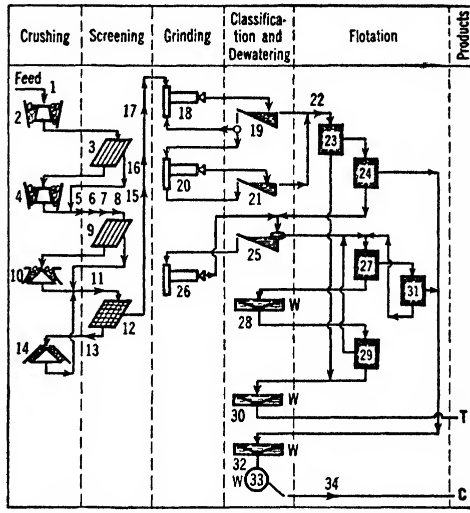
Improvement in production technique may, in general, be prognosticated with safety; but further prognosis that such improvement can be translated into profit is to ignore recent evidence. This is that as technological advance decreases the expenditure of labor and supplies, the price of labor, and the costs of insurance and taxes may be expected to advance at least proportionately.

Presentation of flowsheets. Flowsheets are shorthand methods of telling the story of the routing of a mineral product in a dressing plant. They are varied greatly in form according to the information sought to be conveyed. The simplest form to write and, therefore, the one most commonly used, is that shown in Fig. 1. The same flowsheet, in the graphical form which is the draftsman's delight, and is commonly used in periodicals for its pictorial value, is shown in Fig. 2. The same flowsheet in the abbreviated segregated form used herein is Fig. 3. It was devised to make apparent at a glance the principal operations employed in the treatment scheme, the extent of each operation, the products made, and the points at which they are removed. As applied herein the accessory apparatus of transport, storage, weighing, sampling, and the like are suppressed, in so far as the pictorial scheme goes, but are denoted by numbered arrows which indicate relative location and refer to details in the accompanying parts list.

Condensed flowsheets are useful for study and comparison of practices followed in different parts of mills. A form found useful for crushing is shown in Fig. 4; one for grinding in Fig. 5 and others for grinding in Figs. 73 and 76; one for flotation in Sec. 12, Fig. 58.

Field notes. A flowsheet can be made in the field by any one who has plenty of time, good wind, strong leg muscles, and a reasonable supply of patience and persistence. The normal busy visitor to a plant lacks the time, however; he certainly, in some cases, has passed the age when wind and muscle are expendable; and he is normally accompanied on his round by an official who, though invariably courteous, has work of his own to do on a schedule that does not include step-by-step following of the flow of pulp. Field notes should accommodate to this situation and yet provide a record from which an accurate flowsheet can be drawn at a later date. One scheme that solves the problem is shown in Table 1. The underlying idea is to record each piece of apparatus as it is reached in the

[Text continued on p. 10.]



Legend for Fig. 3:

1. 20- and 30-cyd. side-dump standard-gage cars from mine.

2. 1 @ 48-in. gyratory, 200-hp. motor, belt drive.

3. 4 grizzlies, 2-in. spaces, 70-lb. rail.

4. 4 @ No. 8 gyratories, 75-hp. motors, Tex-rope drives.

5. 2 @ 36-in.×1,130-ft. conveyors in parallel, 51-ft. rise, 290 f.p.m., 75-hp. motor with speed reducer, magnet, self-propelled clutch-type trippers.

6. 1 @ 15,000-ton circular steel bin; manganese-steel gates to tripper cars.

7. 4 @ 24-in.×225-ft. gathering belt conveyors in parallel, 450 f.p.m., 10-hp. motors with speed reducers, fed by tripper cars from floor of bin; conveyors C4, C5, C6, 3A in series.

8. 2 @ 7,400-ton circular steel bins, sliding gates, apron feeders; conveyors 4.

9. 4 bar-type grizzlies, 2-in. spaces.

10. 4 @ 7-ft. standard cone crushers, 300-hp. synchronous motors, direct-connected.

11. 4 @ 28-in. conveyors, 750-ton circular steel screen surge bin.

12. 48 vibrating screens.

13. Conveyors, 750-ton circular steel surge bin.

14. 6 @ 7-ft. short-head cone crushers, 250-hp. synchronous motors, Tex-rope drive.

15. Conveyors, 16,000-ton suspended-steel bin.

16. Conveyor.

17. 8 conveyors.

18. 16 @ 6×15-ft. ball mills, 23.1 r.p.m., 300-hp. synchronous motors direct-connected through magnetic clutch.

19. 16 @ 78-in. simplex spiral classifiers (one to each mill), 3 1/2 r.p.m., 7 1/2-hp. motors with speed reducers.

20. 16 @ 6×15-ft. ball mills, 23.1 r.p.m., driven as (18).

21. 16 classifiers as (19).

22. 2 @ 5-launder tub distributors.

23. 10 @ 62-ft. Hunt-Dunn air-lift flotation machines.

24. 1 @ 12-ft. Hunt-Dunn machine.

25. 3 @ 13-ft. bowl-rake classifiers, 6 r.p.m., 18 s.p.m.

26. 1 @ 8×12-ft. ball mill, 12 r.p.m., 300-hp. synchronous motor.

27. 1 @ 38-ft. Hunt-Dunn machine

28. 2 @ 60-ft. thickeners in parallel.

29. 1 @ 62-ft. Hunt-Dunn machine.

30. 1 @ 275-ft. and 2 @ 200-ft. traction thickeners in parallel.

31. 1 @ 21-ft. Hunt-Dunn machine.

32. 2 @ 60-ft. thickeners in parallel.

33. 4 @ 14×14-ft. drum filters, 2 @ 8 1/2-ft. 7-disk filters, in parallel.

34. Conveyor to railroad cars to smelter.

tour, regardless of its place in the general order of flow, and to note at the place of record the plant name of the machine, the source or sources of its feed, and the destinations of its products. The amount of detail to be recorded at the time depends on circumstances. For ease in working up the notes it is best to group all notes concerning individuals of a given type of machine, *e.g.*, crushers, or classifiers, together. It is convenient to have the notebook suitably ruled as in Table 1 before starting, and to give each class of machine a separate page. Table 1 is built on an imaginary trip through the New Cornelia mill (Figs. 1 and 2) with Mr. Barker, the courteous but somewhat hurried guide; table and trip started with the primary ball mills, and the field record comprised the entries in all columns of the table except those for numbers, which are filled during office work-up. A field check of all items except transport is readily available by queried verification of the totals in the "Description" columns for the different classes of machines, *e.g.*, 14 flotation cells, 15 crushers, etc.

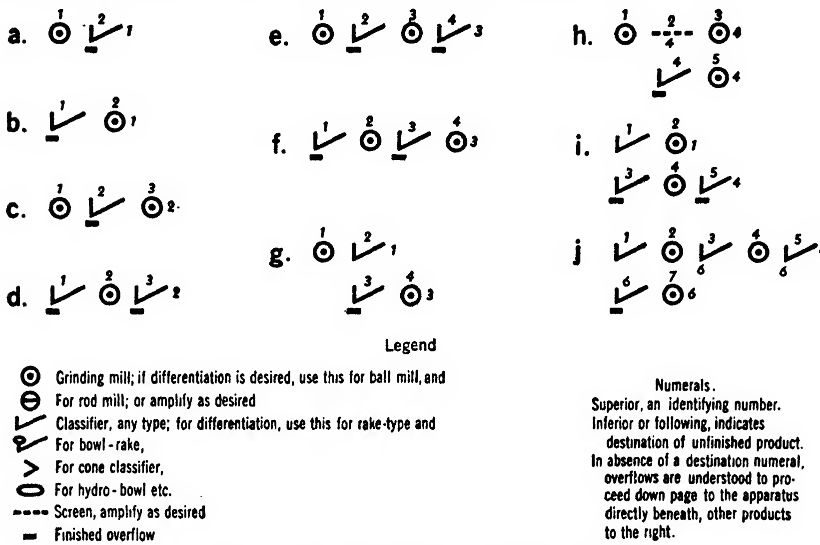

Fig. 5. Condensed flowsheets for grinding circuits.

Work-up starts, assuming that it is made by a different person than the field man, by searching the column "Source of feed" for the entry "Mine." In the present case this is found on page 6 of the notes ("Transport") and the corresponding machine ("Dump cars") is numbered 1 in the left-hand column; the destination of the product is at the same time numbered 2 in the right-hand column. Turning to p. 1, the primary gyratory is now given the number 2 assigned to it on p. 6, the destination of its product is numbered 3, and its source 1.

Subsequent numbering may be done most easily if construction of the flowsheet is carried along simultaneously. Taking as an example the form of flowsheet used in this book (Fig. 3), the sheet is ruled with vertical columns for segregation of the symbols designating the principal classes of machines, in the present case Crushing, Screening, Grinding, Classification and Dewatering, and Flotation, and a final column for Products. No column is provided for transport or storage; these are indicated by numbered arrowhead marks at the places where they appear in the flow.

Referring now to p. 6 of the field notes, item 1 is the dump cars and is indicated on the flowsheet by the correspondingly numbered arrowhead on the flow line starting from the word "Feed." At the same time, item 1 of the Legend is entered. Item 2 of the flowsheet is next drawn and the corresponding entry made in the Legend. The primary grizzly is now numbered 3 on p. 2 of the field notes, is indicated as shown on the flowsheet, its description entered in the Legend, and the destination of the oversize ("Secondary gyratory") is numbered 4 in the last column of p. 2 of the field notes, the source number being filled in at the same time. The destination of the undersize of the grizzly is left unnumbered for the present. The secondary gyratory (p. 1 of field notes) is now numbered 4 (destination 5 and source 3), and the corresponding entries of item 4 made on the flowsheet and Legend, with the proper connecting lines drawn in. Items 5, 6, 7, 8, and 9 are next handled successively as indicated. At this time the line indicating the undersize of item 3 can be drawn in by reference to item 3 undersize (<) on p. 2 of the field notes, Conveyor 1 having, by this time, been identified as item 5. Continuing with the oversize of item 9 through 10 and 11 to 12 now permits the line for undersize of 9 to be drawn. When the path of the oversize ends with the delivery of the product of the short-head crushers (item 14) to the screen surge bin (item 11), the undersize of item 12 is picked up, and its destination is assigned the next number (15). From item 15 to item 23 the procedure is as before. The flotation cells (items 23, 24, 27, 29, and 31) are arranged on the plan that successive floats of a given stream are pictured successively along a vertical line on the flowsheet, while refloat operations are pictured along lines moving to the right. Thus the diagram in the Flotation column shows at a glance one float only on the primary stream, three successive floats on the rougher concentrate with regrinding and thickening

intervening, and one recleaning. The choice, at each flotation stage, of the stream to follow is a matter of convenience in drawing the diagram, that item being chosen for the next number which best lends itself to shortest flow lines on the drawing. Water returned to circulation is indicated by W in order to eliminate flow lines.

A final check should be made by comparing field-book entries with the completed flowsheet, when all source and destination numbers in the field book should appear on the flowsheet, and all source-number and destination-number places in the field book should show filled.

Check list. Notes should start with the date, location, and name of informant. These are the three items apparently most easily forgotten by any busy man. General items of importance are: LOCATION of dressing plant with respect to supply, market for product, and waste disposal; ORE: Mineralogical composition, assay, hardness, size, special characteristics affecting milling; WATER: Source, composition (if any chemical operations are involved in dressing), quantity available and consumed, transport, methods of reclamation; POWER: Source, nature, consumption, reliability; LABOR: Source, nature, consumption; TRANSPORTATION OF FEED AND PRODUCTS: Distances and methods; MILL BUILDING: Site, type, material; PERFORMANCES: Assays of products, recovery; COSTS: Detailed, over-all. For specific machines and processes the details wanted vary. The following list is suggestive.

CRUSHER: Maker, type, size, set, throw, speed, tons new feed per hr., circuit, % circulating load, power installed and consumed, method of drive, size of feed and product (screen tests or limiting apertures), method of feeding, material and life of wearing parts, miscellaneous technical or operating data, costs.

The essential subject matters for any machine are: Identification, conditions of operation, performance, and cost.

Condensed mill flowsheet, without detail, is useful for purposes of record. It should present only the primary data. Such a flowsheet for the mill of Figs. 1, 2, and 3 is given in Fig. 5*A*, using the conventions of Figs. 4, 5, and Sec. 12, Fig. 58.

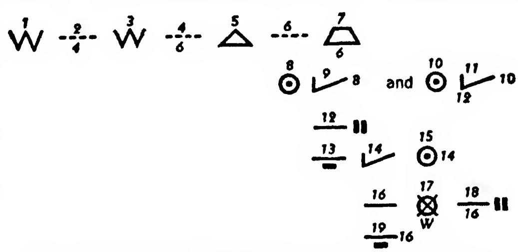

FIG. 5*A*. Condensed flowsheet corresponding to Fig. 3.

Production; prices; uses. District, state, national and world production are obtainable from publications of the U. S. Geol. Survey, the U. S. Bureau of Mines, the U. S. Department of Commerce, and various technical publications. Summaries of such data for 1938 are shown in Figs. 6 and 7. Study of these, together with average prices over a period of years, obtainable from the same sources, furnishes a basis for judgment as to the market for dressed products, possible competition, etc. Knowledge of uses will tell something as to the probable stability of demand, wide and varied use tending toward stable, increasing demand.

The early increase in the use of closed bodies for automobiles resulted in a great increase in the demand for aluminum, which the shift to pressed-steel and the possibility of the use of plastic bodies in turn decreased. Centralization of power production together with the electrification of long stretches of railroad resulted in increased demand for copper and aluminum. On the other hand, the enormous and relatively high grade copper deposits of Central Africa are a definite damper on any great increase in copper prices, barring political manipulation. The tremendous increase in knowledge of alloys in the last decade has jumped demands for the rare metals, demands which may be expected to increase.

The grade or physical character of certain concentrates, such, for instance, as zinc, molybdenite, and lead, is highly important in determining price. The smelter is the direct buyer of concentrating-mill products. Its charges for treatment, and its scale of payment for metals, while based ostensibly on its own costs and upon market prices for metals respectively, actually are the result of bargaining with the producer on the fundamental basis of what the traffic will stand. Hence the actual return to the producer in a particular case is not to be estimated safely until at least a preliminary skirmish with the smelter has been concluded. (See Art. 50.)

General bibliography for metals and metallic minerals follows:

8. *Metal statistics*, American Metal Market, N. Y., Annual.
9. *Minerals in world affairs*, T. S. Lovering, Prentice-Hall, Inc. (1943).

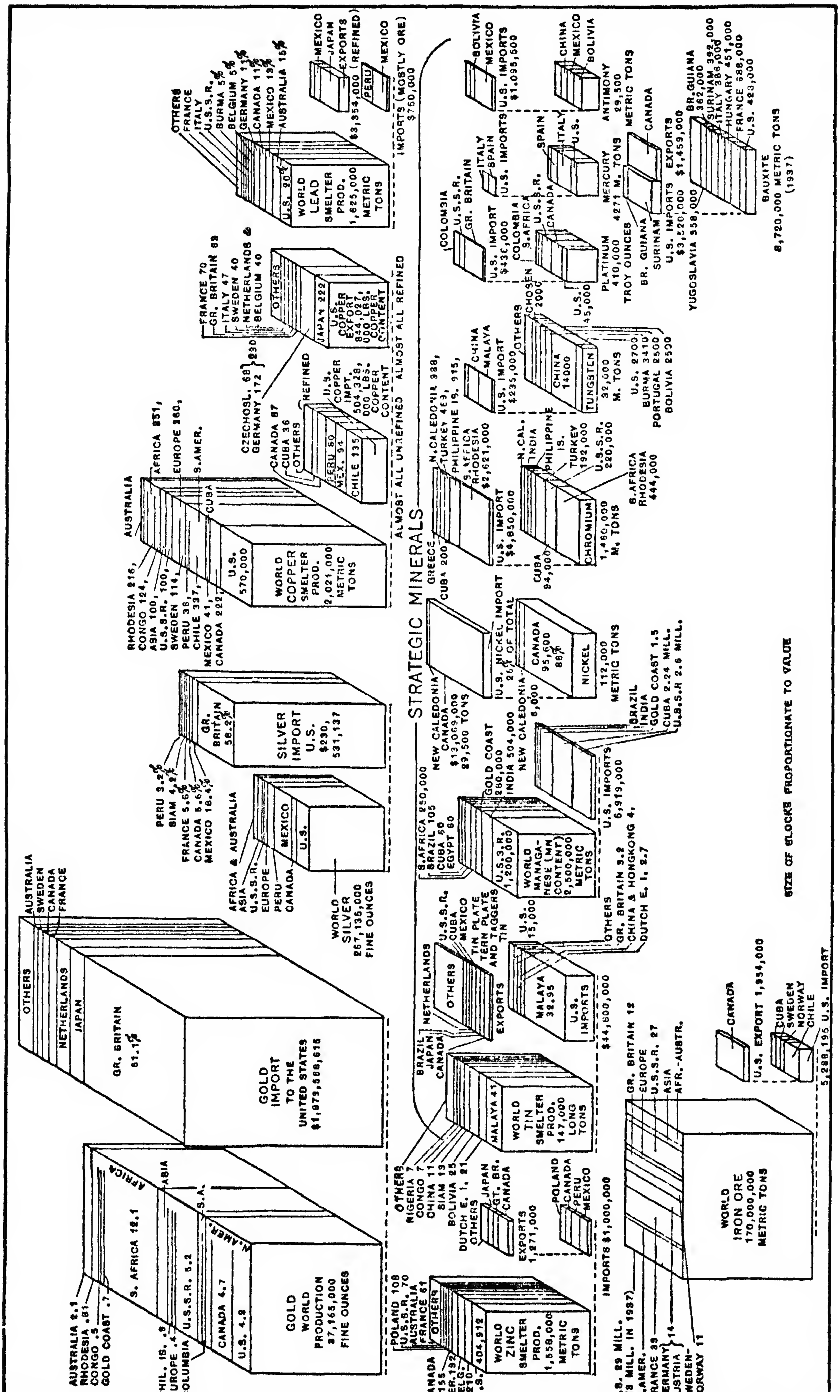

FIG. 6. World production of metallic minerals in 1938, together with U. S. imports and exports (*after Ruisz, 22 MMt 159*).

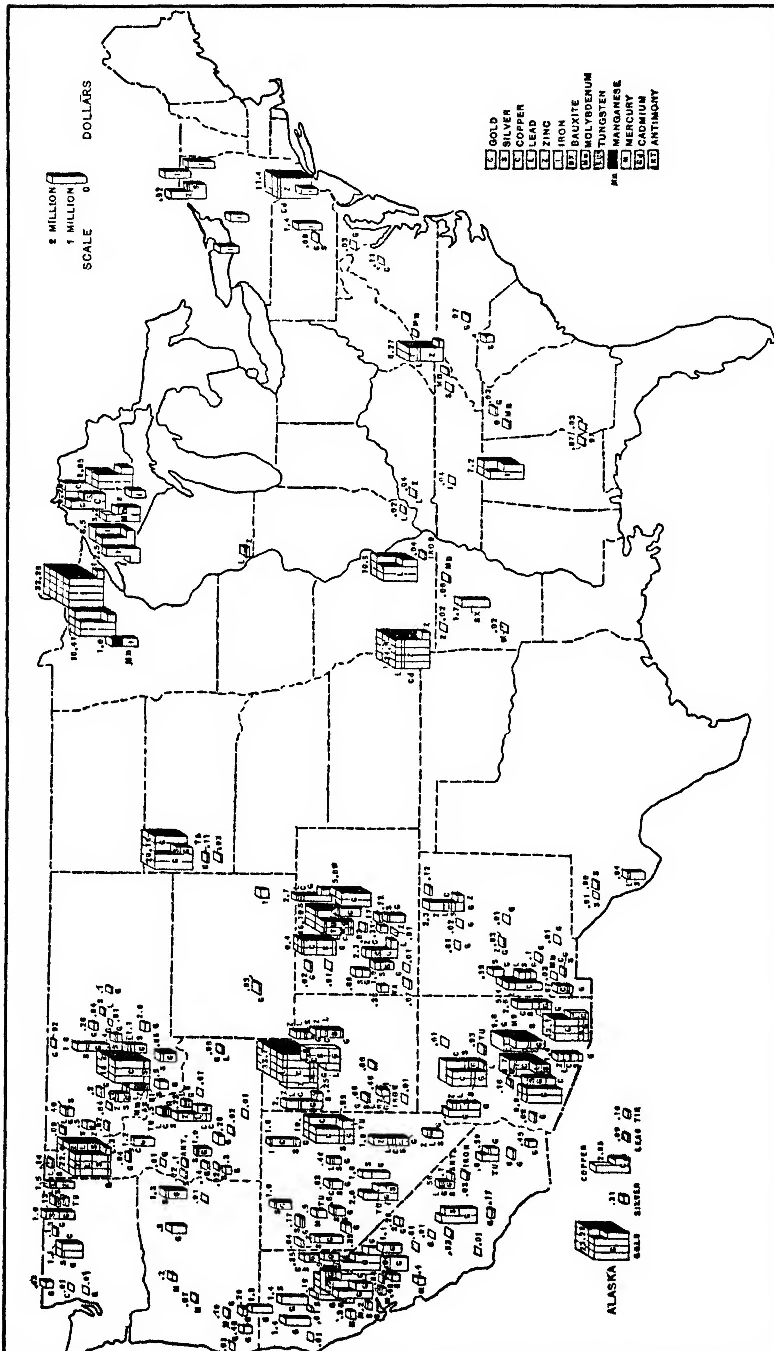

Figures indicate recovered values in millions of dollars.

FIG. 7. Production of metallic minerals in U. S. in 1938 (*after Raisz, 22 MMt 159*).

Ore. The quantity and quality of ore available, either actually blocked out in the mine or positively indicated by geologic data, determine not only whether a mill should be built but are also important factors in the problems of capacity and type of construction. The mineralogical character of the ore is controlling as to the treatment scheme. Capacity is determined by potential mine capacity, first cost of construction, and demand for the product. Type of construction is determined by kind and size of machinery, probable life of mine, and relative costs of different materials. See also Sec. 20.

Mineralogical character is important from the standpoints of distribution of the different minerals and relative quantities, as well as from their actual chemical nature and physical characteristics. It not only limits the number and kinds of processes available, but it determines at what grain sizes they may be applied and is an important element in determining whether or not they should be applied at one size and not another. For example, sphalerite cannot be recovered from a barite gangue economically by gravity or magnetic concentration, but flotation will make a ready separation. If, however, the sphalerite is coarsely disseminated, so that a considerable quantity of barite is free at, say, 3- or 4-in. size, it will almost certainly pay to hand-pick barite, even though such coarse tailing may be somewhat higher grade than would be made by flotation. The reason is that crushing and grinding from this size to flotation size and floating will cost 20 to 25 cents per ton at the best, and there would be further savings due to the increase in mill capacity thus effected.

Many similar but less clear-cut instances are to be found in the following flowsheets. The most interesting are those such as galena in lead-zinc ores and pyrite-chalcopyrite in copper ores substantially free of precious metals, where the aggregation of the galena and of the pyrite-chalcopyrite is coarse enough to permit gravity separations, and where, of course, separation by flotation is also possible. The decision has been, almost universally, against stage concentration; jigs and tables have been removed from many mills which had them installed originally, on the ground that the tonnage of concentrate removed was so small that not enough increase in grinding-mill and flotation capacity was effected to justify the expense of step concentration. But the question is now being reviewed in many mills and has been resolved in favor of early removal of concentrate in some of them. In gold mills such a decision has been almost universal.

The important physical characteristics of the ore minerals are specific gravity, magnetic permeability, and hardness.

Specific gravity. The important consideration is the CONCENTRATION CRITERION, *i.e.*, the ratio of the specific gravity of the heavy mineral, decreased by the gravity of the fluid in which separation is attempted, to that of the light mineral similarly decreased (*e.g.*, for galena and quartz in water $\frac{7.6 - 1}{2.6 - 1} = 4.1$). If this criterion is greater than two, reasonable separation can be effected without difficulty; if the ratio is less than 1.5, it is difficult, and, if less than 1.25, substantially impossible. With a criterion of 2.5, it is possible to get clean concentrate, but difficult to get low-grade tailing, and the tonnage of middling is large. With a criterion of 3 or more, gravity concentration is easy in all sizes down to the finest sands. No difference in specific gravity that exists between minerals is sufficient to make clean gravity separation of slime possible; with such fine particles the relation of surface to volume (and weight) is so large that the surface forces resisting settlement of the particles in fluids are sufficient to mask or completely nullify the effect of specific gravity. (See Sec. 15, Art. 3.) See Sec. 11.

Magnetic concentration is employed under two general conditions, *viz.*, (1) when the valuable mineral is magnetite, (2) when the valuable and waste minerals are close together in specific gravity, not amenable to sharp separation by flotation, and one is sensibly permeable to magnetic lines of force and differently permeable from the others. Magnetic concentration of highly permeable minerals can be practiced at all sizes below 2-in.; if the minerals are of low permeability, fine crushing is necessary. See Sec. 13.

Hardness. Differences in hardness as between valuable mineral and gangue are not utilized to any appreciable extent today in metal concentration, with the one exception of residual ores, where a clay-sand matrix is selectively disintegrated by water plus a little mechanical action, and separation is subsequently effected on a size basis. But see Sec. 14, Art. 11.

Hardness differences are important in many nonmetallic separations (Sec. 3).

Chemical composition is important from the concentrating standpoint for the reason that the selective effect in flotation is dependent (with minor exceptions, for which see Sec. 12, Art. 3) upon selective chemical reactions between the ore minerals and the flotation reagents in water. Hence the mineral to be floated must have a definite but relatively slight solubility in water, or be capable of chemical surface change to a soluble form, while the less soluble the gangue is the better. Water solubility of the necessary magnitude, either as natural mineral or as a spontaneously oxidized product thereof, is a property of

most nonsilicate minerals and of a few silicates. The relatively insoluble silicates and quartz are the most abundant gangues. See Sec. 12.

Other mineral characteristics occasionally utilized in concentration are COLOR and LUSTER, in hand sorting (Sec. 14, Art. 2); FRACTURE, in mechanical picking (Sec. 14, Art. 4), and in certain tabling and jigging operations (Sec. 11); ELECTRICAL CONDUCTIVITY, in electrostatic separation (Sec. 13, Art. 9); natural SIZE, in placer gravels; DECREPITATIVE PROPERTY; INTERFACIAL ENERGIES, as in diamond saving on greased tables (Sec. 12, Art. 17), or preferential partial SOLUBILITY in organic liquids, as in the Trent process (Sec. 12, Art. 15), or in inorganic liquids, as in amalgamation (Sec. 14, Art. 5).

Ratio of concentration. If the ratio of concentration (Sec. 19, Art. 24) of an ore is high, the flowsheet should be of such character that concentration is effected at one size, in order to reduce the variety of concentrating machines and to permit use of large units with correspondingly low capital and operating charges. Under such circumstances the crushing plant may be greatly simplified, a minimum number of screens and classifiers is necessary, and expensive elevation and horizontal transport of pulp are greatly lessened. The all-flotation porphyry-copper mills are typical of this type of flowsheet. If coarse tailing can be discarded and ultimate fine grinding is necessary, as, for instance, is the case at the MESABI IRON CO. (Fig. 90), ALASKA GASTINEAU (*Ed. 1, p. 124*), and AMERICAN ZINC (Fig. 102), some elaboration of flowsheet is justified in order to save the cost of grinding low-grade material. If the ratio of concentration is low and, as usually follows, the valuable mineral occurs in coarse aggregates, a complicated flowsheet with a multiplicity of screens, classifiers, and concentrating machines of varied types may be justified, on the grounds that coarse concentrate is usually of higher grade than fine, is more cheaply and efficiently smelted, that an appreciable tonnage is diverted from the grinding machines, and over-all recovery is bettered. The basis of the final statement is that a particle of, say, a size that would go into coarse-jig concentrate will, if broken, form some slime particles, and, since the recovery of slime particles is never perfect, a part of this broken particle is discarded as tailing, with resultant lowering of recovery. If slime recovery is efficient, this argument has but little weight, and inclusion of a coarse-concentrating machine must be justified on the first three grounds mentioned. Flotation is so efficient, and the size that can be handled on shaking tables has increased so greatly in recent years, that jigs have been eliminated from many mills Such elimination, in addition to simplification of flowsheet, permits removal of several screens and saves water, labor, considerable maintenance, floor space, headroom and may even lessen the total power consumption. Tables are almost always used with ores of low ratio of concentration, if gravity concentration is feasible, even when flotation is most efficient; the flotation machines can make a lower-grade tailing with low-grade than with high-grade feed, some burden is taken off the grinding machines, and the cost of dewatering granular table concentrate is much less than that for flotation concentrate.

Rich ores both require and can stand the cost of more elaborate treatment than poor ores; large ore bodies justify not only larger but more elaborate mills than small; and valuable substances such as gold, silver, and tin can, economically, be pursued further, *i.e.*, according to a more elaborate flowsheet, than lead, zinc, or iron. When freight rates are high or smelter penalties for impurities great, extensive (and expensive) treatment designed to raise the grade of concentrate is justified, or high-grade concentrate may be made at the expense of a low recovery, while with low concentrate-treatment and transportation charges, the flowsheet should be designed for high recovery, with less attention to the grade of the final product.

Tonnage is an important factor in flowsheet design. If tonnage is small, say less than 500 tons per 24 hr., the simplest type of flowsheet, only, should be considered, even when a resulting low ratio of concentration might indicate an elaborate mill. Multiplication of machines under such circumstances makes for small and relatively inefficient units and increases capital and operating costs out of proportion to the savings otherwise effected. When tonnage is large, a mill is designed in independent sections, the flowsheets of which are substantially the same, the tonnage going to each section being determined usually as that of the largest-tonnage unit or convenient group of units. The advantages of such design are: (1) that it permits one or more sections to be shut down for repairs, curtailment, or the like without affecting the efficient operation of the remainder of the plant, and (2) that responsibility for efficient operation of machines can be localized and a competitive spirit engendered among the workmen. Capacity is readily increased by adding sections without materially affecting current operations. Within any given section, experience indicates that operating and overhead costs decrease with increase in size (and capacity) of machine units up to the point where efficiency of the machine, operating or mechanical, begins to fall with further size increase. This follows from the fact that volume of machine working space tends to increase as the cube of linear machine dimensions, while first cost

increases in proportion to a figure between the first power and the square; that attendance is in almost direct proportion to the number of units rather than to their size; and that power consumption, while theoretically dependent only on the tonnage of material acted upon, actually increases for a given tonnage with decrease in size of the treatment units because of corresponding multiplication of seats of friction losses. Multiple sections permit study of new equipment and operation without too serious interference with the operation of the plant as a whole.

Water supply. Scarcity of water may dictate dry treatment when otherwise wet treatment is indicated; it may make it necessary to plan for a smaller daily tonnage than otherwise; and it usually requires inclusion in the flowsheet of a more or less elaborate water-reclamation system.

Essential elements of a flowsheet are crushing, grinding, concentrating, concentrate handling, sampling and weighing, storage, transportation of pulp, and tailing disposal. The first three of these elements, in any flowsheet, are primarily dependent upon the ore as delivered from the mine; concentrate handling depends upon the method of concentration and upon the after-treatment of the concentrate; sampling and weighing are matters of efficient mill control; storage and pulp transport are solely mechanical features, substantially independent of the character of the ore and of the process of concentration, but of supreme importance from the standpoint of smooth and efficient operation; tailing disposal may mean simply extending the tailing launder far enough away from the building so that it will not under-cut foundations, or it may involve elaborate water reclamation, sand-slime separation, dam-building, etc., to the extent of a sizable cost element. Prevailing trends, as indicated by the flowsheets, are presented in the following paragraphs.

Crushing is normally done in two or three stages, depending primarily upon the reduction necessary from run-of-mine maximum to grinding-mill feed-size, but secondarily upon capacity, additional machines being provided in series rather than in parallel in the majority of mills. Departures from the 2- or 3-stage norm are unusual and correspond to unusual conditions; low capacity is the ordinary explanation for a 1-stage plant, step concentration by gravity or magnetic methods or carry-over of an old crushing plant in a mill where such methods were formerly practiced explains the 4- and 5-stage mills.

Jaw and gyratory crushers are the usual primaries; metallic ores are, in general, too hard for other types. Gyratories with widely flaring heads, of reduction-gyratory or cone types, are almost universally found as secondaries. In 3-stage plants the final stage is about equally divided between rolls and high-speed flared-head gyratories, with the more recent choices probably leaning toward the gyratory type, but with the question of superiority far from settled when the last stage is in closed circuit to produce 1/4-in. maximum or finer.

Screening. In plants where no concentration precedes the grinding circuit the question of screens in the crushing plant is solely one of crushing and grinding efficiencies. It seems to be fairly well established that the maximum capacity of a crusher to crush particles coarser than its discharge opening is decreased by the presence of fines in the crusher feed, and that steel consumption is also higher with fines present. If crushers are oversize, the additional capacity is not needed, and headroom loss and screen operation may easily cost more than the saving in crusher steel. Most large plants scalp the feed to both primaries and secondaries; the trend in the smaller plants is not pronounced.

Closing circuit on the final crusher with a screen is the predominant practice, indicating almost universal recognition of the fact that tramp oversize in grinding-mill feed disturbs uniform operation, and that uniformity of operation is an essential prerequisite to efficiency; departures are almost all found in the small plants, where operating efficiency may not be as important as first cost, or in plants using large ball mills and feeding at relatively coarse sizes. The closing screen almost invariably serves to scalp the feed.

Use of screens in the grinding circuit is rare, but recent experimentation (Sec. 5, Art. 12) indicates possible economies where finished size is not too fine and differential grinding of heavy minerals is not desirable.

Grinding of the primary pulp stream is one- or two-stage, with choice definitely favoring one-stage work. Two stages are found where open-circuit rod mills are called upon to do the end of the crushing job and the beginning of grinding. Two-stage closed-circuit work is difficult to balance, and is rare, except when a very fine product or exceptionally hard ore seem to require it. See Sec. 5, Art. 12.

Regrind of middling is common, and may be carried out in several stages, depending in part upon requirements as to concentrate grade and in part upon the difficulty in making satisfactory tailing.

Concentration. There is less concentration at coarse sizes than simple considerations of technology and economy would seem to dictate. Where it is applicable, the entire job is generally done by flotation, and very cogent considerations seem to be necessary to cause departure from the custom. The reason seems to be that this makes for a simpler mill, less specialized knowledge is required of the labor crew, hence more machines can be put under a given man, and the small sacrifice in metallurgical efficiency is more than compensated for by reduction in pay-roll.

The usual scheme of concentration, whatever the specific method, is roughing out a middling on the primary pulp stream, and cleaning, with or without regrinding as necessary, to the grade desired. The extent to which the roughing treatment on the primary stream is carried is proportional, in general, to the unit value of the metal sought.

Storage. More or less adequate storage is provided in most plants, the degree increasing, in general, with the size of the mill. The important points are: (1) between mine and mill, to smooth out

irregularities in mine-production rates; (2) between the crushing and grinding plant, to permit independent operation on an entirely different time schedule, if desired; (3) in the crushing plant to eliminate surging in the feeds to secondary crushers and fine screens; (4) directly ahead of the grinding mills, to permit constant feed thereto (this is effected by the provision noted under 2 above); (5) ahead of gravity and magnetic separators, to eliminate feed surges; (6) in flotation circuits, to give time for conditioning and promoting reactions, to smooth out rates of variation in feed assay, and to maintain reasonable constancy in the bulk feed rate to the cells and consequently in the treatment times.

Transportation of dry pulp is almost invariably by means of conveyors of the belt or articulated-plate type (pan or apron), the latter being used for very coarse material or where the conveyor must resist dumping impacts. Fine wet pulps are just as invariably pumped. In the coarse wet range, *e.g.*, for heavy circulating loads in primary grinding-mill circuits, bucket elevators of the wheel or belt type are favored over pumps, owing to smaller tendency to clog, and greater accessibility when a clog-up occurs.

Concentrate handling in flotation plants is almost standardized, comprising thickening in tanks by sedimentation and filtration of thickened pulp, with discharge of cake either directly into railroad cars or into bins. In a few smaller plants the thickener is eliminated. Granular concentrate is almost invariably dewatered initially by some form of mechanical classifier, usually of the drag or spiral type, with the sand product discharged into a draining bin suitably lined and otherwise guarded to prevent loss of fine concentrate with the drainings.

Tailing disposal, when this involves impounding and water reclamation, follows the pattern of preliminary dewatering, at as high an elevation as possible to minimize the cost of pumping back water; and transporting the thickened pulp by pipe (usually wood-stave) or launder to the impounding site, where a rough sand-slime separation is made, the sand is deposited so as to form a dam with minimum rehandling, and the slime is carried back into the pond. Additional water may be collected here by overflow weirs and seepage tunnels.

Properties of metals are given in Table 2. For properties of minerals see Sec. 22, Table 46.

3. ALUMINUM

Uses. Aluminum alloys are used for plates, structural shapes, and castings where lightness is essential, principally in airplane, automobile, and railway car construction. Aluminum foil has wide use in packaging butter, tea, cigarettes, etc., electrical transmission, cooking utensils, corrosion resisting vessels, and in crumpled form for heat insulation. The metal is also used in scientific instruments, alloys, lithographic work as a substitute for stone or zinc, deoxidation of steel in casting, Thermit welding, as a coating for steel plate, in explosives, as powder for paints and printing inks, etc. Bauxite, besides its use as a source of metallic aluminum, is used for manufacturing aluminum chemicals, for filtering and decolorizing petroleum fractions, for making abrasives such as Alundum, and for refractories.

Ores. Aluminum is widely distributed as a large constituent of many different minerals, but extraction is commercially possible at present only from bauxite and cryolite. Bauxite occurs as pisolites and claylike masses in pockets or lenses in residual clays. Cryolite occurs as lenses or veins in metamorphic rocks. At present bauxite ores form practically the only commercial source of aluminum. Principal economic occurrences of bauxite in the United States are in Georgia, Alabama, and Arkansas. Principal foreign localities are France, Italy, Dalmatia, Surinam, and British Guiana. Analyses range from 50 to 60% Al_2O_3, 2 to 20% SiO_2, 1 to 25% Fe_2O_3, and 1 to 3% TiO_2.

Production statistics are given in Tables 3, 4, and 5.

Selling. See Art. 50. PRICES (N. Y.) for 99% + virgin ingot metal over the period 1930–1942 have dropped steadily from 23.79¢ to 15¢ per lb.

Treatment. Practically all the bauxite now mined is of sufficiently high grade so that no mechanical separation from associated minerals is necessary. In the past, loose mixtures of bauxite and clay have been concentrated in log washers, but the low-grade deposits cannot compete at present. Treatment at one large plant consists in coarse breaking, the hard rock in gyratories, the soft in Fairmount crushers; followed by drying in coal-burning rotary kilns, about 7×50-ft., at a temperature near 1,100° F.; thence to a cooling conveyor and shipping bins. Residual mechanically held moisture is from 0.5 to 1%. The bauxite also contains from 15 to 33% combined water, which, if the ore is to be used for abrasives and refractories, is driven out by heating at about 2,000° F. in 6×60-ft. kilns, leaving a total moisture content of about 0.5%. Simpler methods of the same general character are followed at smaller plants. Some mines ship the ore as mined, but this is extremely uneconomical, if the haul is long, on account of the high water content.

Aluminum metal is obtained from high-grade bauxite by leaching with aqueous alkali, precipitating $Al(OH)_3$ from the extract, and calcining to Al_2O_3, which is electrolyzed. Metal grades range from 94 to 99.9% Al, according, principally, to the amounts of Fe and Si carried into the electrolytic cell.

A method of producing Al from low-grade siliceous iron-bearing bauxites and from certain clays is proposed by Klein (*PhD thesis, CU, 1941*). It makes use of the fact that ferric chloride is selectively abstracted from aqueous HCl solutions of Fe^{+++} and Al high in chlorides by water-immiscible organic solvents such as *n*-butyl acetate. Evaporation of the residual aqueous solution and calcination of the resulting $AlCl_3 \cdot 6H_2O$ produces Al_2O_3 of sufficient purity for electrolysis.

4. ANTIMONY

Uses. Antimony metal has little or no use as such. The principal use is in alloys such as Babbitt metal, Britannia metal, shrapnel lead, hard lead for plumbing and similar purposes, type metal, white metal, pewter, storage-battery plates, solder and various other soft metals used in making foil, metal tubes, etc. Antimony persulphide is used in vulcanizing rubber, the trisulphide for safety matches, and the powdered metal, trioxide, and trisulphide are all used for pigments.

Ores. The economic minerals are STIBNITE, SENARMONTITE, VALENTINITE, and CERVANTITE. Ores are found in most countries, but China and Mexico produce two-thirds of the world supply. The Chinese deposits consist of stibnite of remarkable purity, occurring as pockets and bunches in dolomitic limestone.

Production. See Table 6.

a Metal content of ore produced.
b Total exports, regulus, crude, and oxide.
c Metal, sulphide, and oxide produced.
e Asia Minor.
f Includes Greece, Morocco (Sp.), Canada, Spain and Portugal, Union of S. Africa, Japan, Hungary, Austria, Bulgaria, India.

Prices. Average prices per lb. f.o.b. New York from 1930 to 1942 have ranged: 7.67¢ (1930), 5.62¢ (1932), 15.35¢ (1937), 12.35¢ (1938), 15.55¢ (1942).

Treatment (*8 AIM 196*). Only high-grade ore is mined, most of which is sufficiently concentrated by crude hand picking. If further concentration is necessary, it may be effected readily by liquation at a low temperature. Both methods are extremely wasteful (liquation losses may run as high as 30% antimony) but only high-grade material can be shipped from isolated districts to the smelters, and even in the period of high prices during 1914–1918 it was considered more economical to bear the losses attendant upon these crude methods than to practice more refined (and hence more costly) concentration methods.

Antimonial or hard lead containing 10 to 20% Sb is obtained as a by-product in smelting and refining antimonial-lead concentrate.

Bolivian antimony mines (*2 #4 FMQ 39*) are small; the sulphides occur in small quartz veins in black slate; gold is frequently present. The MALLIRI mill, near Challapata, concentrates by hand sorting, crushing in a quimbelete, hand jigging and buddling, in order, making 75 tons per mo. of 65%-Sb concentrate. At COBIJA near Oro Ingenio, the treatment comprises, in order, a sorting floor with hand jigs and buddles, a Krupp ball mill for middling, jigs and tables. In general losses are high owing to the attempt to make high-grade concentrate (60 to 65% Sb) and costs (1939) ranged from $20 to $30 per ton of concentrate, of which about 40% was for labor.

Methods used to recover metal from concentrate comprise roasting to oxide and subsequent smelting of the oxide in crucibles or small reverberatory furnaces with soda ash and charcoal (see *Bray; Hayward; Liddell*).

5. ARSENIC

Uses. The principal uses are for insecticides such as Paris green and lead arsenate for plant sprays, and calcium arsenate for boll-weevil extermination. Sodium arsenite is used in considerable quantities on railroads and highways as a liquid weed killer. The white oxide is used in glass making to mask the coloring effect of metallic oxides and impart brilliancy. It is also used in making sheep and cattle dips. The red and yellow sulphides are used for pigments in paints, calico printing, dyeing, and tanning. Small amounts of the element are used for certain alloys, principally lead shot.

Ores. Arsenic occurs as a constituent of 30 or more minerals (Hess, *MR, 1914, p. 957*) but the principal sources are arsenopyrite, arsenides, and sulpharsenides associated with ores of lead, copper, and the precious metals, the arsenic being a by-product. Arsenopyrite is mined for the arsenic content in a few places. Realgar and orpiment occur as vein minerals associated with barite, stibnite, quartz, pyrite, and precious metals, but there is little or no mining of such deposits for arsenic content.

Production. See Table 7.

Treatment. Arsenical fumes and dust from bag houses and Cottrell precipitators in lead and copper smelters are calcined or roasted in reverberatory or special furnaces and the fume condensed in an ordinary flue system. This fume is known as black dust and contains about 90% As_2O_3. It is refined to >99% As_2O_3.

Table 7. World production of white arsenic (thousands of metric tons) (*MI*)

6. BERYLLIUM

Uses. Metallic beryllium and most of the alloys in which it is a major component are brittle. A Cu-Be alloy (*ca.* 2.25% Be in which the Be acts as a precipitation hardener) is being used where the properties of the alloy will justify its high price. The alloy can be manipulated untreated, and when heat-treated possesses great strength, high resistance to fatigue, wear and corrosion, combined with good electrical conductivity and nonsparking characteristics. The principal uses so far developed are for springs, high temperature valves, motor-brush holders and collector rings, and tools. Alloys with aluminum, nickel, and other metals are also available. The first are becoming important in the airplane industry. Beryllium oxide and other compounds are used in small quantities in glass and ceramic glazes, in super-refractories, and as high-duty abrasives.

Ores. The total amount of beryllium in the earth's crust is probably equal to the total of copper, lead, and zinc combined. Commercial minerals are beryl, $3BeO \cdot Al_2O_3 \cdot 6SiO_2$ (one variety of which is the gem emerald) and phenacite, both of which are found in many pegmatite dikes, but the minerals contain low percentages of Be, and few pegmatites contain over 1% of the metal.

Production comes from U.S.S.R., Germany, France, and Brazil. Scattered deposits are found in S. Dak., Pa., N. Y., N. H., Mass., and Conn. The U. S. Bureau of Mines estimates 1937 production of metallic beryllium at not over 15,000 lb.

Prices (1941): \$47 (lump) and \$50 (cast bars) for metal 96%+ Be. Also sold as alloys with Cu, Fe, Ni, or Al at substantially the prices of the contained Be plus the price of the alloy metals.

Treatment. No method of concentration other than cobbing and hand sorting of relatively coarse crystalline beryl has been practiced, but flotation of beryllium mineral experimentally has been described (Sec. 12, Art. 53). Present methods of treatment of concentrate comprise reaction with acid to form a water-soluble salt, *e.g.*, $BeSO_4$ or Na_2BeF_4; concentration of this salt as by fractional crystallization or preferential precipitation; reduction from salt to metal by carbon or by electrolysis. For detail see *Hayward; Bray.*

114026

7. BISMUTH

Uses. Metallic bismuth is used almost exclusively in making low melting-point alloys with tin, lead, cadmium, and mercury. Bismuth compounds are used extensively in medicine. They find some use also in porcelain and glass making, and in pigments.

Ores. The principal minerals are the native metal and bismuthinite, bismite, and bismutite. The principal deposit of the world is in Bolivia, where bismuthinite occurs in veins associated with tin and silver minerals. Native bismuth and bismuthinite commonly occur in veins associated with pyrrhotite, pyrite, molybdenite, wolframite, and precious metals. Native bismuth is sometimes found in sluice boxes. Carbonates and oxides of bismuth occur as residual deposits from leaching of rocks containing primary bismuth minerals. In such occurrences the bismuth is often associated with clays.

Production. Domestic production is never reported. In 1937 it was probably substantially increased owing to increase in lead-smelting activity. Imports of metal were 56.7 short tons in 1936 and 51 tons in 1935 as against a range in the preceding 8 years of 3.5 to 23.8 tons. The principal foreign producer is Peru, 381 metric tons in 1936 as compared with about 165 tons each from Canada and Mexico. Other scattered production is reported from Bolivia, Japan, Spain, and Australia.

Treatment. Domestic sources are lead- and tin-refinery slimes. These are fused with caustic soda and soda ash (also sodium sulphide if Cu is present); cast into slabs and electrolyzed in an acid solution of $BiCl_2$ with Bi or graphite cathodes. If the crude is a sulphide concentrate, this is roasted to drive off As, Sb, and most of the S and then smelted in a small reverberatory in a reducing atmosphere with carbon (and iron, if much S is present). See *Bray; Hayward; Liddell.*

8. CADMIUM

Uses. Principal uses are in making alloys of low-fusing temperature; as an alloy with Cu for use in transmission lines and other places where added strength and hardness are important; in type metal; as a deoxidizer in some nonferrous alloys; in electroplating hardware, automobile parts, and the like by the Udylite process, to resist rusting; in the standard Weston cell; in accumulator cells; as a constituent of Cd-Ni bearing metals; in photography; and, in the form of sulphide, as a yellow or orange pigment.

Ores. Cadmium is obtained both in this country and abroad exclusively as a by-product from zinc smelting and refining, or from baghouse dust at lead smelters where zinc is a constituent of the ores treated. Siebenthal (*MR*, 1921) states that cadmium occurs in all zinc ores in the proportion of about 1 of cadmium to 200 of zinc.

Treatment. Fractional distillation of blue powder and refractionation of the distillate; or solution of the oxide in acids and precipitation of the metal chemically or electrolytically. For detail see *Liddell.*

Production. See Table 8.

Prices (per lb.): 1932, 55¢; 1938, 80¢; high in 1937, $1.60.

9. CAESIUM

Uses. No commercial uses are recorded; it has some use in scientific laboratories.

Occurrence. The only mineral containing a large proportion of Cs is pollucite (35% Cs_2O), a rare constituent of granite on the island of Elba, and at Hebron, Me. Cs is a fairly common but minor associate of the other alkali metals in salt beds, brines, ashes, cement flue dust, etc.

Treatment. Analytically, Cs, Rb, and K can be separated from Li and Na by differences in their chloroplatinates, or alums; Cs from Rb by the same means, by oxalates or tartrates, or by the slightly soluble double salts of Cs with Pb, Sb, or Sn (*II Mellor, 451; Liddell*).

10. CERIUM

Uses. Cerium metal added to molten cast iron is said to aid oxidation of impurities, increase fluidity, and increase hardness of the casting. Ferrocerium (63% Ce, 35% Fe) is a pyrophoric alloy. Ce-Al and Ce-Mg alloys cast well and are hard. Cerium acetate has mildew- and moth-proofing properties; the fluoride protects textiles against acids and corrosive vapors; the nitrate is used in gas mantles and in tanning, and in dyeing and printing textiles; the oxide is used in special ceramics and optical glasses, and in nail polishes; the sulphate is a useful catalyzer, and is also used in photography; the tungstate is a catalyst for organic reaction, and improves the brilliancy of carbon lights (flaming electrodes).

Occurrence. In monazite sands, Art. 43.

Treatment. Chemical treatment of the sand concentrate. See *Liddell.*

11. CHROMIUM

Uses. The rapid growth in the use of chromium plating and of "stainless" steels (usually carrying 14 to 18% Cr) has greatly increased the demand. Ferrochrome, an alloy composed chiefly of iron and chromium, with small amounts of carbon, silicon, and other impurities, notably manganese, is widely used for hardening steel for railway wheel tires, wearing parts in crushing machinery, and other steels where toughness and hardness are essential. Chromite bricks are highly refractory and are used for furnace linings. Chromates and bichromates are largely used as red, yellow, and green pigments for dyeing, calico and wall-paper printing, painting, and pottery. Chromium compounds are largely used in tanning and to some extent in medicine. Use of stainless steel and rustless iron, both containing 12 to 14% Cr, is increasing rapidly. Chromizing by a process similar to zinc sherardizing and aluminum calorizing has been accomplished, and chromium plating is well established. Both chromized and chrome-plated iron and steel resist atmospheric and sulphur corrosion; the latter resists acid and ammonia fumes but not electrolytic corrosion in mineral acids.

Ores. Chromite ($FeO \cdot Cr_2O_3$) in highly basic igneous rocks or in serpentine is the only ore. The natural mineral is rarely pure chromite, Cr_2O_3 being replaced by Al_2O_3 or Fe_2O_3. As a consequence, the highest grade of ore contains only about 55% Cr_2O_3 and the Cr_2O_3 content in salable ores runs down from this figure to 38 to 40%. American chromite concentrate is usually picotite $(MgFe)O \cdot (AlCr)_2O_3$ instead of chromite; it is not suitable for making ferrochrome. There is a possibility, however, of displacing ferrochrome by the electrolytic metal; this would tend to keep down the carbon content of the alloy, which would be especially desirable with Cr alloys.

Production by countries is given in Table 9. Normal domestic production has been negligible on account of import competition from high-grade deposits, but considerable low-grade ore is available, and war-time plants have been built (1943). Russia, Rhodesia, Turkey, and the Union of South Africa are the major producers.

Selling. See Art. 50. Prices of ferrochrome (60–72% Cr), per long ton: 1932, $154 (low, $120); 1939, $156.

e Estimated.
f Includes Bulgaria, Guatemala, Norway, Rumania, Bosnia, Indo-China.
g Year ending Sept. 30.

Treatment. The foreign ores are mostly from high-grade deposits that require no concentration other than hand sorting. Chromium ores respond to simple gravity concentration, and some such concentration is necessary with many of the domestic ores. A typical flowsheet involves crushing and rod milling to 20 *mog*, followed by close hydraulic classification and tabling. A 50% Cr_2O_3 concentrate can be obtained readily unless the chromite itself is of too low grade. Concentrate is sintered with soda ash to form sodium chromate, which is leached out with hot water, evaporated to a concentrated solution, oxidized to dichromate with sulphuric acid, and separated from Na_2SO_4 by fractional crystallization. Dichromate is decomposed to Cr_2O_3 by fusion with S and the oxide reduced to metal by charcoal, Al, or H, or the metal may be deposited electrolytically from a solution of the chloride. See *Hayward; Liddell; Bray*.

Krome Corp.—D.P.C. plants, Fig. 8 (*144 #9 J 63*).

Location: Coos County, Oregon.
Capacity: 2,000 t.p.d. roughing plant; 400 t.p.d. finishing plant.
Ore: Black sands containing chromite, magnetite, ilmenite, zircon, garnet, and other heavy silicates.
Assays: Feed, 3 to 20% Cr_2O_3, average 6%; rough concentrate, 25% Cr_2O_3, Cr/Fe = 1.65; finished concentrate, 40% Cr_2O_3.
Recovery: 85% in gravity mill.
Ratio of concentration: 5 : 1 in gravity mill.
Water: Principally from a nearby creek; 1,500 g.p.m. pump from tide-water 6,000 ft. against 460-ft. head and thence by gravity for standby.
Power: Purchased; comes at 23,000 volts.
Buildings: Two, separated 9 mi.; sites, gently sloping.
Transport: Mine to mill, 500 ft. max., by 12-cyd. Carryalls; gravity mill to magnetic mill, 9 mi. by 10-ton trucks.

FIG. 8. KROME CORP.—D.P.C. plants.

Summary. Disintegration and scrubbing to separate granular material for tabling; table concentrate enriched by dry magnetic separation and flotation to skim out garnet. Zircon-bearing material tabled and concentrate enriched by skimming out magnetic content.

12. COBALT

Uses are as metal, oxide, and salts. Metal is used for STELLITE (an alloy with iron and chromium), high-speed tool steels, cobalt-steel and cobalt-alloy magnets, age-hardening alloys, HARD-FACING alloys for building up worn parts, anodes, and as a bonding material in the manufacture of tungsten-carbide products. Powdered cobalt metal alone or in combination with other metals is used extensively in Europe as a catalyst in the synthetic production of gasoline from coal. As oxide, cobalt finds extensive use in the ceramic industries for imparting a blue color to porcelain and enamels and to neutralize the yellow color due to iron silicates in enamel coatings. The silicate of cobalt, produced from the oxide, possesses a blue color, the depth of which varies with the cobalt content. Cobalt oxide is an efficient catalyst for the oxidation of ammonia. Cobalt salts, principally sulphate, resinate, and lineoleate, are used as driers in the linoleum, paint, and varnish industries; they are also mixed with soil dressings in sheep pastures to combat anaemic diseases. They are useful for electroplating because the metal plates rapidly, and in combination with other metals, especially nickel and chromium, yields deposits unusually bright, hard and durable.

Ores. The principal ore minerals are sulphides and arsenides. Usually the nature and extent of the associated minerals determine the economic value of a cobalt deposit. In the complex cobalt ores at Cobalt, Canada, the cobalt minerals identified are: smaltite, erythrite, and cobaltite, associated with minerals of silver, nickel, arsenic, bismuth, antimony, copper, lead, and iron. The ores carried 2 to 11% cobalt, and from 10 to 10,000 oz. silver per ton. Concentrate shipments from 1930 to 1938 averaged 8 to 10% cobalt; silver content fell from about 2,000 to 50 oz. per ton. In 1941 the concentrates averaged 10 to 15% Co and 25 to 50 oz. of silver. The ores in Northern Rhodesia and Belgian Congo contain copper sulphides; cobalt content ranges from 2 to 4%. Flotation, permitting the mining of lower-grade ores, has increased ore reserves. Each of the African companies is reported as capable of producing at least 2,500 tons of cobalt metal annually should the market demand that quantity.

The ores of French Morocco have not as yet been fully developed beyond about 1,000 tons per year. The ore ranges from 20 to 55% arsenic, 10 to 15% cobalt, 0.5 to 6% nickel, traces of copper, and considerable gold.

Production was 4,800 tons in 1939 (calculated on cobalt element). Northern Rhodesia produced 30%, Belgian Congo 30%, French Morocco 20%, Canada 15%, Burma 5%, and smaller quantities from Finland, Sweden, and New Caledonia. In 1940 only about 10 to 15% of all cobalt produced was in the form of oxides. In 1941 cobalt was produced in the United States from African ores concentrated in smelting to a copper-cobalt-iron metallic residue containing 40% cobalt. Canadian concentrate is mostly shipped to refineries in the United States.

Selling. The cobalt products of Cobalt, Canada, are offered for sale at prices ranging from 70¢ per lb. of cobalt in 8% cobalt ores to $1.10 per lb. in 14% cobalt concentrate. The copper-cobalt-iron alloy produced from the ores of Africa until the end of 1939 was shipped to Belgium, but recently shipments of the alloy have been made to the United States and Canada for recovery of the cobalt. The ores of Morocco were until 1940 shipped to Belgium for preliminary treatment, and the final treatment of refining was completed in France.

The selling price for cobalt metal (98% Co) in the form of rondelles and shot has been quite steady at $1.50 per lb. In 1929 cobalt metal sold at $2.50 per lb. Black cobalt oxide (70 to 71% Co) has ranged from $2.10 (1929) to $1.10 (1932) to $1.84 (1940), with gray oxide (75% Co) about 10¢ higher. Cobalt in the form of organic salts sells at: resinate, 3 1/2% Co, 17 1/2¢; lineoleate, 8.5% Co, 33¢; and sulphate, 20% Co, 65¢ per lb.

Treatment. Standard metallurgical treatment for arsenical cobalt ores of Canada was to roast to remove arsenic, then smelt the roasted product in a blast furnace to produce high-silver cobalt-nickel-iron speiss, and additionally metallic silver buttons, from high-grade ores. Roasted speiss was dissolved in acid and the various metals precipitated separately, leaving cobalt oxides, which were later reduced to metal.

The copper-cobalt sulphide ores of Northern Rhodesia and Belgian Congo are concentrated and smelted, producing a high cobalt-copper-iron converter slag. The slag is reduced in electric furnaces, giving a metal alloy, containing about 40% Co, 40% Cu, and 20% iron and a slag free from cobalt and copper. The alloy is treated with acid, the copper and iron removed, and the cobalt finally precipitated.

The arsenical cobalt ores of French Morocco are subjected to the standard treatment for arsenical ores, and the gold contained is recovered from the acid-treated residues.

13. COLUMBIUM

Uses. There is no extensive use for the pure metal; it has been patented as a "getter" in radio-tube manufacture; it is chiefly employed, in the form of ferrocolumbium (55 to 60% Cb), as an addition to chrome and chrome-nickel steels, in which columbium restrains the loss of corrosion resistance, due to intergranular precipitation of carbides, upon continuous exposure to high temperature. For full effect, about 10 times as much Cb as C should be present (*113 A 126, 143*). The presence (usually unavoidable) of tantalum in a ferrocolumbium employed for this purpose is not essentially objectionable, but since tantalum is only about one-fourth as effective as the same weight of columbium (Ta should be 30 to 40 times C) and is about 5 times more valuable, producers of the ferro-alloy naturally prefer high-Cb, low-Ta concentrates.

Ores. Columbium and tantalum (Art. 41) almost always occur together, varying proportions of their oxides combining, as acids, with such bases as Ca, the rare earths, U, Mn, and Fe. The minerals most nearly free from tantalum are samarskite, wöhlerite, pyrochlore, euxenite, fergusonite, and columbites from Greenland and Nigeria; in other columbo-tantalum minerals, tantalum usually predominates. Ti, Zr, Ge, Sn, and W are frequent impurities. The columbite-tantalite group—(Fe, Mn) $(Cb, Ta)_2O_6$—is the commercial source of both metals; these minerals form a continuous and isomorphous series from columbite (theoretically 21% FeO + MnO; 79% Cb_2O_5; sp. gr., 5.36) to tantalite

(13.9% $FeO + MnO$; 86.1% Ta_2O_5; sp. gr., 7.03). Certain species of the group possess magnetic susceptibility. These minerals are normally associated with granites and pegmatites. For the electric-furnace production of ferrocolumbium, a columbite should contain at least 60% Cb_2O_5, and not more than the following percentages of other oxides: Ta_2O_5, 10; TiO_2, 5; FeO, 15; SiO_2, 5; MnO, 5; SnO_2, 0.20.

Production. World's supply of low-Ta columbite now comes from Nigeria, where it is recovered concurrently with alluvial tin; a considerable part of the output has been extracted from the waste dumps of earlier tin operations. Nigerian output, in long tons: 1937, 707; 1938, 530; 1939, 431. A tin producer at Manono, Katanga, Belgian Congo, follows a similar procedure, and reported 105 tons of Cb-Ta ore shipped in the year ending June 30, 1939. Imports of columbium ore by United States, in short tons: 1937, 461.3; 1938, 322.5; 1939, 54.5; average value, $685 per short ton.

Prices of ore are subject to negotiation. In 1939, ferrocolumbium (50 to 55% Cb) sold for $2.25 to $2.35 per lb.

Treatment. Ordinary processes as applied to alluvial tin ore (Art. 44). Columbite from lode mining could be treated by the same method as is applied to tantalite, at Tinton, S. Dak. At Kailo, Belgian Congo, mixed tantalo-columbites (sp. gr. 5.5 ~ 7) are separated from a cassiterite gravity concentrate by lifting out first the garnet and then the Ta-Cb minerals with high-intensity magnets. (*PC*, N. A. de Kun.)

14. COPPER

Uses of copper are multitudinous. It is, under most circumstances, the most economical conductor of electricity and hence is used widely for electrical machinery and transmission; its resistance to corrosion by air, water, and weak acids makes it valuable for certain parts of structures such as roofing, gutters, window screens, ship bottoms, for cooking utensils, and for pipes and containers in chemical and manufacturing plants. It is the main constituent of many alloys, notably brass and bronze which, like copper, can be drawn, and, unlike copper, can be successfully cast and, being harder than copper, can be worked in a lathe. Copper chemicals such as the sulphate, carbonate, cyanide, etc., find wide use in the arts, and as germicides and fungicides.

Ores. The economic minerals are atacamite, azurite, bornite, bournonite, brochantite, chalcanthite, chalcocite, chalcopyrite, chrysocolla, native copper, covellite, enargite, cuprite, malachite, melaconite (tenorite), and tetrahedrite. Copper is found in practically every type of ore deposit and associated, in one place or another, with practically every metallic and rock-forming mineral. The largest and best-known deposits are the sulphide-vein deposits of Montana, the native-copper deposits of the Lake Superior region, the "oxidized" and "porphyry" deposits of the southwestern United States, and the oxide and sulphide deposits of Belgian Congo and Northern Rhodesia. At Butte, Mont., the ore-bearing veins occur in granite, the chief copper minerals are chalcocite, enargite, bornite, and chalcopyrite, and the principal associated vein minerals are quartz and pyrite; minor minerals are covellite, tetrahedrite, tennantite, sphalerite, argentite, gold, and minerals containing bismuth, tellurium, selenium, nickel, and manganese. In the Lake Superior region the native copper, associated with native silver, occurs as part of the cementing matter in a conglomerate, as a cavity filling in lava beds, and in veins cutting both igneous and sedimentary rocks. The usual gangue minerals are calcite and zeolites. The "oxidized" deposits of the southwest carry large amounts of the oxidized copper minerals, malachite, azurite, and cuprite, and directly below or closely associated with these, bonanzas of massive secondary chalcocite. Both classes of minerals are derived from the primary copper sulphides, largely chalcopyrite and cupriferous pyrite, which are found unaltered in greater depths. The deposits occur in limestone or at limestone-porphyry contacts. There are also numerous granitic intrusions associated with the ore-bodies which have caused the formation of characteristic contact minerals. These deposits are characteristic of the Bisbee and Clifton districts. The deposits of the Jerome district differ markedly. Here bornite and chalcopyrite occur in fissures and as impregnations in slate country rock near intruded igneous dikes. The "porphyry coppers" are mineralized zones in granitic porphyries and schists. The principal copper mineral is chalcocite, which occurs as grains and veinlets in the country rock. Pyrite, chalcopyrite, and magnetite are the principal metallic associates; quartz and the rock-forming silicates form the nonmetallic gangue. An enormous disseminated deposit containing soluble sulphates of copper occurs at Chuquicamata, Chile. Enormous deposits of high-grade oxidized and sulphide copper occur on both sides of the border between Belgian Congo and Northern Rhodesia in the Katanga district; the oxidized deposits are surface residuals; the sulphides are finely disseminated in more or less metamorphosed and silicified sedimentary rocks, shale, quartzite, and dolomite, the principal copper mineral near the top of the sulphide zone being chalcocite, changing gradually to chalcopyrite and bornite with depth.

Production statistics are shown in Tables 10 and 11.

Selling. See Art. 50. Average prices, electrolytic copper, ¢ per lb.: 1929, 18.35; 1932, 5.79; 1936, 9.71; 1937, 13.39; 1938, 10.22.

Treatment of copper ore depends upon the nature of the ore itself. There are three general methods, *viz.*, (1) direct smelting for high-grade ores, containing upward of 6% copper; (2) leaching followed by electrolytic precipitation or precipitation by iron, for oxidized ores; (3) concentration followed by smelting of concentrate, for low-grade sulphide and native-metal ores. Concentrate is smelted in reverberatory furnaces, with or without prior roasting, forming a mixture of copper and iron sulphides (MATTE), which is drawn off molten and sent to a converter; here it is blown with air, which first oxidizes the iron, causing it to slag off as a silicate, and thereafter oxidizes the copper sulphide to crude metallic copper; this is then refined electrolytically. For details of treatment see *Metallurgy of Copper*, Newton and Wilson, John Wiley & Sons (1942); *Copper Metallurgy*, by various authors, Vol. 106, A.I.M.M.E. (1933); *Bray; Hayward; Liddell.*

Copper-Ore Concentrators

All copper ores except those containing the metal in sulphate or silicate form are amenable to concentration by methods presently known. The native-copper ores respond read-

ily to water-gravity concentration in the gravel and sand sizes and to flotation of slimes; sulphides are almost invariably treated by flotation; the oxides and carbonates can be floated or oil-air tabled in the sand sizes without much difficulty, but the slimes tend to be refractory. The sulphates and silicates and the slime oxides and carbonates respond best to leaching. Reduction of the oxidized mineral to metallic copper, either by a reducing roast or by solution in water and subsequent precipitation, followed by flotation, is readily done in the laboratory and has been done in a few mills (Fig. 39).

Flowsheets of copper concentrators are, on the whole, remarkably similar, when the wide variety of ores, of smelter and freight schedules, and of available treatment methods are considered. Thus copper ores may contain native copper, or either of the three sulphides, chalcocite, bornite or chalcopyrite, as the principal value-bearing constituent; in which case a given weight of copper-bearing mineral will carry respectively 100, 80, 56, or 35 parts of copper per 100 parts of pure concentrate, with corresponding limitation on the highest possible grade of concentrate that can be made. Workable ores normally range from 0.8% copper upward, although few run higher than 6 to 7% and the new MORENCI plans to send 0.5% ore to the mill. More or less oxidized copper mineral, cuprite, tenorite, malachite, azurite, brochantite and chrysocolla, usually accompanies the sulphides. Gangues range from pure quartz to substantially pure massive iron sulphides. Gold in more or less important quantities is a relatively common metallic associate. The valuable minerals occur in all sizes of grain from submicroscopic to masses of many pounds. Each of these variable conditions would, considered from a purely technological standpoint, determine a more or less unique treatment for a given ore, and act as a natural limitation to the result attainable. Additionally, some mills are adjacent to smelters while others must ship concentrate several hundred miles; each smelter offers a different schedule of net payments made up of a complex of varied charges and allowances. As a consequence, a set of entirely extraneous economic limitations is imposed on concentration technology. Yet despite the multitude of combinations of controlling conditions thus made possible, copper concentrators may not only be correctly described generally as comprising crushing, grinding, and flotation, but, more specifically, as employing 2- or 3-stage crushing, 1- or 2-stage grinding, and a rougher-scavenger float with 1- or 2-step cleaning. Few plants fall outside this specific description. The exceptions are those treating ores containing native metal, copper or gold, which plants usually include more or less gravity concentration, to remove the coarser metal particles; the plants treating ores in which intergrown sulphides of copper and iron occur in relatively coarse grains, wherein slightly greater complexity is found in the flotation treatment, and an extra, later grinding stage may be added; and the plants in which gold occurs in both copper and iron sulphides, in which case separate flotation sections may be employed to make separate concentrates.

Crushing is predominantly 3-stage, comprising almost universally a jaw or gyratory as the primary machine, a standard cone as the secondary, and the third stage rolls or short-head cones in substantially equal numbers of cases, with a few mills using rod mills. Scalping by grizzly ahead of the primary crusher and by vibrating screen ahead of the secondary is usual (substantially universal with wet ores); the final stage is closed or open circuit depending on the size of grinding-mill feed and whether the grinding circuit has ample capacity; closure is normally by a vibrating screen which precedes the final crusher and scalps its feed. With soft ores and relatively coarse dissemination of sulphides, 2-stage crushing is practiced when the run-of-mine is not too coarse. At RAY the open-stage rod mill is, in effect, a third crushing stage; at MOUNTAIN CITY and MAGMA the sulphides are coarse-grained and present in considerable bulk, rendering the feed relatively friable, and low-grade concentrate is acceptable. Power consumption for crushing averages about 3.5 hp-hr. per ton. Cost of crushing from run-of-mine to 1/4-in. averages from 6 to 8¢ per ton, and to 10-m. from 9 to 12¢.

Grinding. Primary grinding is 2-stage at 8 out of 15 mills, 1-stage at 6 and 3-stage at one; present trend is toward one stage. Of the multistage circuits, the first stage is open in 5 mills; the final stage is closed in all. In general, closed-circuit multistage grinding corresponds to the harder ores and finer disseminations, but MIAMI is an exception on both counts. Arrangement of mills and classifiers is highly variable; no generalizations are justified. The *mog* of the primary grind ranges from 48 to 65, with most of the work near the finer end. Sizing-assay tests and microscopic examination of tailings show that most sulphide-copper losses are in the very fine sizes and that much of this is free copper mineral (Sec. 12, Art. 35). Whatever the reason for this loss, one remedy lies in so arranging the grinding circuit that overgrind of sulphides is minimized. Clean classification of sands, high circulating loads in the grinding circuit, a primary desliming classifier with high-density overflow, the use of gravity concentration in the grinding circuit, and the addition of small amounts of collector and frother to the grinding circuit are all expedients directed to this end.

Power consumption averages from 11 to 12 hp-hr. per ton.

Cost of grinding and classification from 1/4-in. to 48 or 65 *mog* ranges from about 8 to 30¢ per ton and averages between 15 and 18¢.

Flotation. Roughing is predominantly rougher-scavenger flow, with middling recirculated to the rougher, in several cases through the final primary-grinding unit. Cleaning practice varies somewhat. With simple ores sufficiently coarsely disseminated to permit copper-iron severance in the primary grind, or when copper-iron separation is unnecessary, one cleaning is the rule. When bulk floats are

made in the rougher, two cleanings are usual, one of which may precede iron depression, in which case the tailing of the final cleaner is an iron concentrate. If bulk float is reground before separation, primary cleaning is normally multistage, and regrinding may either precede or follow the first stage of such cleaning. Counterflow of cleaner middling is normally one-stage. Ethyl xanthate is the usual collector, pine oil the usual frother, lime the principal depressant for iron, with cyanide used when chalcocite is an important copper mineral. Power consumption averages 4 to 5 hp-hr. per ton. Cost ranges from 5 to 25¢ per ton and averages between 10 and 12¢.

Concentrate handling is almost universally thickening followed by filtration of thickened product on drum or disk filters. Cake moistures range from 6 to 10%. Cost per ton of original feed varies, of course, with ratio of concentration, and ranges about 1/2¢ to 6¢ per ton.

Tailing disposal ranges in elaborateness from simple gravity discharge through a short launder as at BRITANNIA to elaborate thickening, pumping, and dam building as at MIAMI. Costs range from substantially nothing to 8 or 10¢ per ton.

Recoveries range from 85 to 90% of the sulphide copper with the low-grade ores when iron is depressed, and from 90 to 97% for the higher-grade feeds, reaching the higher figures when iron is acceptable in concentrate. Sulphide tailing on low-grade feeds ranges from 0.05 to 0.1%; it will run to 0.2 to 0.3% with high-grade feed.

Grade of concentrate ranges from 35 to 50% Cu when chalcocite is the principal copper mineral and iron elimination is desirable; corresponding grades for chalcopyrite are 25 to 30%. When iron is not eliminated, either because of its salability or because of gold content, grades run down to 10 to 15% Cu (MAGMA, MT. MORGAN).

Power consumption ranges from 13.5 hp-hr. per ton at RAY and 13.9 at ANDES, with relatively soft ores and large daily tonnages, to the high twenties at MOUNTAIN CITY and MAGMA, with low tonnages, and at MT. MORGAN and MT. LYELL, where gold recovery requires more persistent chasing of values. The two native-copper mills reported, using both gravity concentration and flotation, consume upward of 30 hp-hr. per ton.

Water consumption in the sulphide mills is 2.5 to 4 tons per ton of ore without water recovery; it can be held down easily to about 1.25 tons with a moderate recovery installation.

Labor duty varies widely, ranging from about 20 to 100 tons per man-shift operating. The lower figures are for the smaller mills, while the higher figures represent about the best that can be done today (1942) when treating large tonnages with well-trained labor. Average duty is about 35 tons.

Costs average (1935–1940) about 50¢ per ton milled, dropping to 30¢ at United States mills treating large daily tonnages of simple ores and rising to $1 to $1.50 at smaller mills with difficult ores. Average for 15 mills in United States in 1930's (some at reduced tonnages) was 60¢ per ton, of which labor constituted about 30% and power 25%.

15. NATIVE-COPPER MILLS

Native copper ores are milled in the Michigan peninsula and at a few localities in Bolivia, notably Coro Coro. The ores present problems unique in concentration practice on account of the size and toughness of the metallic particles. Special crushing equipment must be employed, and, although metallic copper is readily floatable, the coarse copper must be removed as it is freed. Hence hand picking, coarse and fine jigging, and tabling are employed, with grinding and flotation in the scavenging role. Recoveries are about the same as those at sulphide-copper mills treating ore of the same grade; costs are somewhat higher.

Copper Range Co. Fig. 10 (*Q* by A. L. Engels, Sup't).

Location: Freda, Mich.

Ore: Amygdaloid containing native copper in relatively coarse aggregation together with native silver; also some cuprite, malachite, azurite, and chrysocolla; gangue minerals principally quartz, calcite, and epidote.

Capacity: 1,320 tons per 24 hr.

Assays: Feed, 2.73% Cu; concentrate, 61.7%; tailing, 0.066%.

Recovery: 96.5%.

Ratio of concentration: 23.4 : 1.

Labor: American and foreign. Tons per man per 24 hr.: Operating, 35; repairs, 265.

Running time, principal causes of loss: Replacement of wear plates.

Water: Pumped 1,600 ft. from Lake Superior; 125 hp. installed. Consumption, 7 tons per ton of ore milled. None reused.

Building: Steel and concrete. Concrete floors slope 1/4 to 5/8 in. per ft. in wet parts. Sloping site. Heated.

Machinery handling. Manual crane, chain blocks on mono-rails. Air hoist.

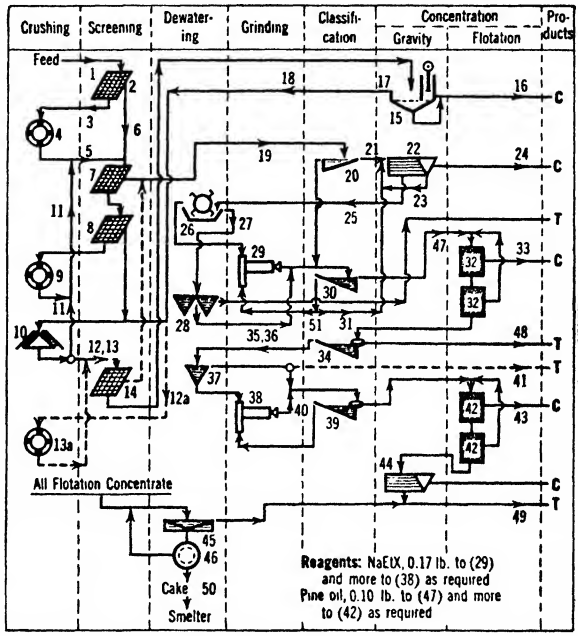
Power: Purchased. Comes 45 mi. at 66,000 volts and 15 mi. at 28,500 volts. Motors 2,200-, 440-, and 220-volt, 60-cycle. Consumption, 34.2 hp-hr. per ton of ore milled.

Transport: Railroad at property. Ore comes 14 mi.; concentrate shipped 19 mi., both by rail.

Tailing by gravity through launders to Lake Superior.

Summary. Crushing from 6-in. grizzly undersize to <7/32-in. ball-mill feed in 3 stages, comprising two special impact mills in series in closed circuit with an 11/16-in. screen, followed by a short-head cone in closed circuit with a 7/32-in. screen. A bleed-off of native

copper is provided for in the cone circuit. One-stage primary grinding to 28 *mog* in a simple ball mill-classifier circuit. Concentration starts with the above-mentioned scalping operation on $^{11}/_{16}\sim^{7}/_{32}$-in. material in jigs; all $<^{7}/_{32}$-in. sands are scalped on tables. The flotation circuit comprises 4 successive stages with slime-tailing discard and sand-tailing regrind between stages 2 and 3; each pair of stages is rougher-scavenger routing with finished concentrate from the rougher and one-stage counterflow of middling.



Legend for Fig. 10:

1. In order: 3,000-ton run-of-mine bin; traveling feeder; belt conveyor. Rock size: max. thickness, 6 in., length up to 24 in.
2. 1 @ 4×8-ft. Link-Belt vibrating screen, 1-in. aperture.
3. 54-in. apron picking conveyor, 40 f.p.m. Two men per shift pick mass copper, steel, and wood. About 6% of copper content of rock removed at 2×4-in. up to 18-in. masses.
4. 2 cage-type impact crushers.

FIG. 10. COPPER RANGE CO., Freda mill.

Calumet & Hecla Mining Co. Conglomerate mill. Fig. 11 (*Q* by C. H. Benedict, Metallurgist; *IC 6364*).

Location: Torch Lake, Mich.

Ore: Native copper with a little native silver in an extremely hard rhyolitic conglomerate. Gangue minerals are quartz, feldspar, calcite, epidote, barite, and chlorite. The rock is tough, hard, and highly abrasive.

Capacity: 3,850 tons per 24 hr.

Assays, %Cu: Feed (original mine ore), 3.0; concentrate, 60 to 62.

Recovery: 95%.

Ratio of concentration: 20 : 1.

Percentage possible running time: 98, approx.

Labor: American; 19.5 tons per man-shift, total.

Power: Boiler steam for stamps. Stamp exhaust to turbines generating electrical power for other mill units. Motors 440- and 2,300-volt, 25-cycle. Consumption, 30 to 36 hp-hr. per ton milled.

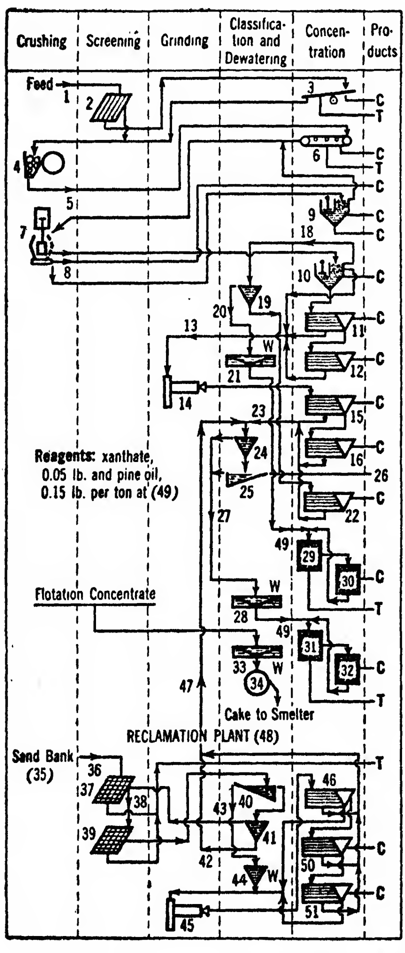
Water: 28 tons per ton milled (not including leaching and flotation). No reclamation.

Tailing: Elevated by centrifugal pump to launder emptying into Torch Lake.

Building: Steel frame, wood sheathing, painted corrugated-iron cover. Level millsite. Heated by exhaust steam.

Distances: Mines to mill, 5 mi., max.; mill to smelter, 0.5 mi.; water at mill; power transmitted 0.5 mi. at 13,500 volts.

Costs: See flowsheet notes (35), (36), and (48) and Table 12.



Legend for Fig. 11:

1. By 7-ton skips in shaft.
2. Grizzly, 4-in. spaces.
3. Tilting pan, 9 ft. wide at upper end and 4 ft. wide at lower; bottom 3/4-in. plate, sides 1/2-in., all lined with 3/8-in. sheet; set at low slope to receive grizzly oversize from a skip load and hold it for picking, then tilted to dump; 2 men per shift, one picking and one on tilting winch.
4. 1 @ 24×48-in. jaw crusher, set 3-in.
5. Bin; railroad cars; bin, 400-ton live capacity, one for each stamp.
6. Picking table.
7. Steam stamp, 3/16-in. screen; 11 of these, each with a mortar jig (Sec. 4, Art. 10). Capacity on conglomerate 335 to 350 tons each per 24 hr. 3 tons water per ton of ore. Air hoist for handling shoes, etc.
8. Mortar-jig discharges. Each mortar has 4 with 4×12-in. sieve compartments, 1-in. screens, 190 to 200 @ 2-in. s.p.m.
9. Bull jig.
10. 2 @ 5-sieve Woodbury jigs (see Sec. 11, Table 20); first sieve 36×48-in., others 30×48-in. Tailing, 140 tons per 24 hr.
11. 2 Wilfley tables.
12. 1 Wilfley table.
13. 50-ft. sand wheel; for 17 units. 2,640 tons per 24 hr.
14. 24 @ 8×72-in. conical pebble mills.
15. 128 Wilfley tables.
16. 8 Wilfley tables.
17. 50-ft. sand wheel.
18. Slime, 160 tons per 24 hr. 1 @ 4-in. slime pump.
19. 2-spigot hydraulic classifier.
20. 110 tons per 24 hr.
21. 1 @ 25-ft. 3-tray thickener. Clear overflow.
22. 1 to 8 Wilfley tables.
23. 50-ft. sand wheel.
24. 16 settling tanks.
25. 8 quadruplex rake classifiers.
26. Leaching plant.
27. 10-in. pump.
28. 12 @ 40-ft. 3-tray thickeners. Overflow clear.
29. Cells 3 to 16 of 4 @ 16-cell 24-in. standard M-S flotation machines; 226 r.p.m. Cells 3 and 4 for preagitation only. Feed: 25% solids; pH 7.0 to 7.5. Time-factor, 16 min. Conc., 15% Cu. See Table 12.

FIG. 11. CALUMET & HECLA MINING CO.

Legend for Fig. 11—Continued:

30. Cells 1 and 2 of (29); 20-min. treatment time. Conc., 30% Cu; tailing, 1% Cu.

31. Cells 3 to 16 of 4 @ 16-cell 24-in. standard M-S flotation machines. Cells 3 and 4 for pre-agitation only. Feed, 25% solids. See Table 12.

32. Cells 1 and 2 of (31).

33. Thickener. Overflow clear.

34. Oliver filter.

35. Old mill tailing, 0.5 to 1.0% Cu. Total cost 1937 per ton of sand treated, including mine and mill administration, was:

General administration and miscellaneous	$0.021
Dredge (note 36)	0.067
Shore plant (notes 37, 38)	0.018
Regrinding plant (notes 39 to 46 and 50, 51)	0.198
Leaching	0.133
Flotation	0.020
Total	$0.437

Tons treated, 1,697,000. Assays, % Cu: feed, 0.560; tailing, 0.097. Recovery, 82.5%

36. Suction-type, 10,000-ton daily capacity. Can dredge to 113 ft. below water level. 20-in. pump with 1,250-hp. motor discharges through 3,000 ft. of 20-in. pipe on pontoons to receiving pool on shore. Cost (1937) for dredge operation with discharge through average length of 3,000 ft. was $0.067 per ton of solid dredged. Distribution was: labor, 26%; power, 32%; pump and pipeline renewals, 32%; other supplies, 10%.

37. Stationary screen on shore, 16×20-ft., 1-in. round holes.

38. Pool, capacity, 20,000 tons sand; 12-in. sand pump, swinging suction of constant length giving uniform feed to plant. Casing is split horizontally and lined throughout. Impeller, 40-in. diam., direct-connected to 200-hp. motor. Receiving box; overflow back to pool.

39. 4 stationary screens, 3/8-in. aperture.

40. 2 double-drag classifiers, each with 2 @ 20-in. belts carrying 6×4×24-in. angles.

41. Settling tanks.

42. 8-in. pump.

43. 22-in.×275-ft. belt conveyor; slope, 2 1/2 in. per ft.; speed, 500 f.p.m. Receiving bin, about 30 min. storage capacity, discharged through gates by means of water jets.

44. Dewatering boxes, clear overflow.

45. 64 @ 8-ft.×18-in. conical pebble mills; total capacity about 3,000 tons per 24 hr. 40-hp. motor on each mill with a flexible coupling and herringbone gears. Mills are served by a 15-ton crane that can pick up a full mill; time to change, about 1 hr.

46. 160 Wilfley tables.

47. 16-in. pump.

48. Cost (1937) from pool to regrinding plant was $0.018 per ton of sand, of which cost 58% was labor, 24% power, and 18% supplies. Cost per ton in regrinding plant in 1937 was:

General expense		$0.0158
Sand conveying and distribution		0.0176
Grinding:		
Labor	$0.0133	
Power	0.0859	
Pebbles and lining	0.0641	
Other supplies	0.0010	
		0.1643
Table treatment		0.0338
Total		$0.2315

Metallurgical results (1937): tons treated, 903,325. Assays, % Cu: Feed, 0.559; tailing, 0.365; concentrate, 40.57. Recovery, 35%. Cost per lb. of copper, excluding smelting and selling, $0.608.

49. 0.05 lb. per ton of sodium xanthate and 0.15 lb. pine oil fed on each stream.

50. 6 Wilfley tables.

51. 4 Wilfley tables.

Concentrate, % Cu	42
Recovery, %	80

Costs, 1937, per ton of slime treated

General expense	$0.017
Slime conveying and distribution	0.025
Flotation	0.042
Royalty	0.010
Total	$0.094
Cost per pound of copper produced, excluding smelting and selling	$0.0115

Summary. No receiving bin. Crushing: Jaw crusher, 24- to 3-in.; steam stamp, 4- to 3/16-in.; pebble mills, 3/16-in. to 35-*mog*. Concentration: Hand-picking on sizes to <3-in.; jigging in stamp mortar and on natural product through 3/16-in. screen, with cleaning of jig-hutch product on shaking tables. Fine sands tabled without classification.

Gravity-concentration residues divided into sands and slimes, the former leached and the latter floated.

Compare with the COPPER RANGE flowsheet. The copper in conglomerate ores is more finely disseminated than that in amygdaloid ores. Leaching eliminates the necessity of regrinding all gravity-concentration tailing to flotation size and makes better extraction of coarse copper than flotation does.

16. MILLS FOR COPPER-SULPHIDE ORES

The methods of concentration applied to sulphide ores of copper depend on the associated metals, and upon smelter contracts and freight rates available, rather than upon limitations imposed by concentration technology. Flotation is the basic method in all cases, and can make a substantially clean copper-sulphide concentrate in the presence of any associated sulphide minerals but galena. But separation from iron is frequently not economically indicated, especially if the smelter is close to the mill, if much siliceous gold ore or concentrate is coming to the smelter, or if the pyrite as well as the copper mineral carries precious-metal values.

Flowsheets range in complexity from the simple 2-stage crushing, one-stage grinding, and essentially one-stage flotation at ANDES to the highly complicated step-grind and regrind, three-sulphide differentiation at NORANDA. MAGMA is unique in retaining tabling in the ball-mill circuit despite substantial lack of precious metal, but the Magma smelter, at the mill, receives much low-iron siliceous gold ore, and the high-iron copper concentrate carries a premium with no freight charge to offset it. On the other hand, MATAHAMBRE, with a smelter 1,200 mi. distant, discards pyrite as completely as possible and makes a concentrate that is close to the theoretical copper content of chalcopyrite, which is the principal copper carrier. UTAH and RAY free pyrite in the original grind and depress it in the roughing operation. At MIAMI and BRITANNIA the sulphides free from gangue at relatively coarse sizes (48 *mog*), but finer grinding is required to effect separation of pyrite from copper sulphides; hence a bulk float is made at the coarse size and tailing is rejected, while rough concentrate is reground and selective separation of copper and iron made thereon. OUTOKUMPO first depresses and then floats free pyrite in the primary run, and depresses locked Cu-Fe sulphides in cleaning, returning them as middling through the grinding circuit to primary flotation. At NEW CORNELIA rough concentrate is reground before cleaning to drop gangue locked in middling grains therein; in general the practice of regrinding before cleaning is growing where high-grade concentrate is economically desirable. Primary slime is separately floated at MT. MORGAN and BRITANNIA; this practice is desirable wherever acidic clayey slimes are present in the ore, as tailing is thus improved with little additional cost in equipment or operation. The sand-slime separation should be made before grinding in order to reduce slime reactions as much as possible.

Andes Copper Mining Co. Fig. 12 (*Q* by O. M. Kuchs, Gen'l M'g'r).

Location: Portrerillos, Chile, S. A.

Ore: Chalcocite, chalcopyrite, tennantite, and pyrite in quartz-diorite porphyry.

Capacity: 16,000 to 17,000 tons per 24 hr.

Assays: See Table 13.

Recovery: Total Cu, 75.2%; sulphide Cu, 94.5.

Ratio of concentration: 29.1 : 1.

Labor: Chilean.

FIG. 12. ANDES COPPER MINING CO.

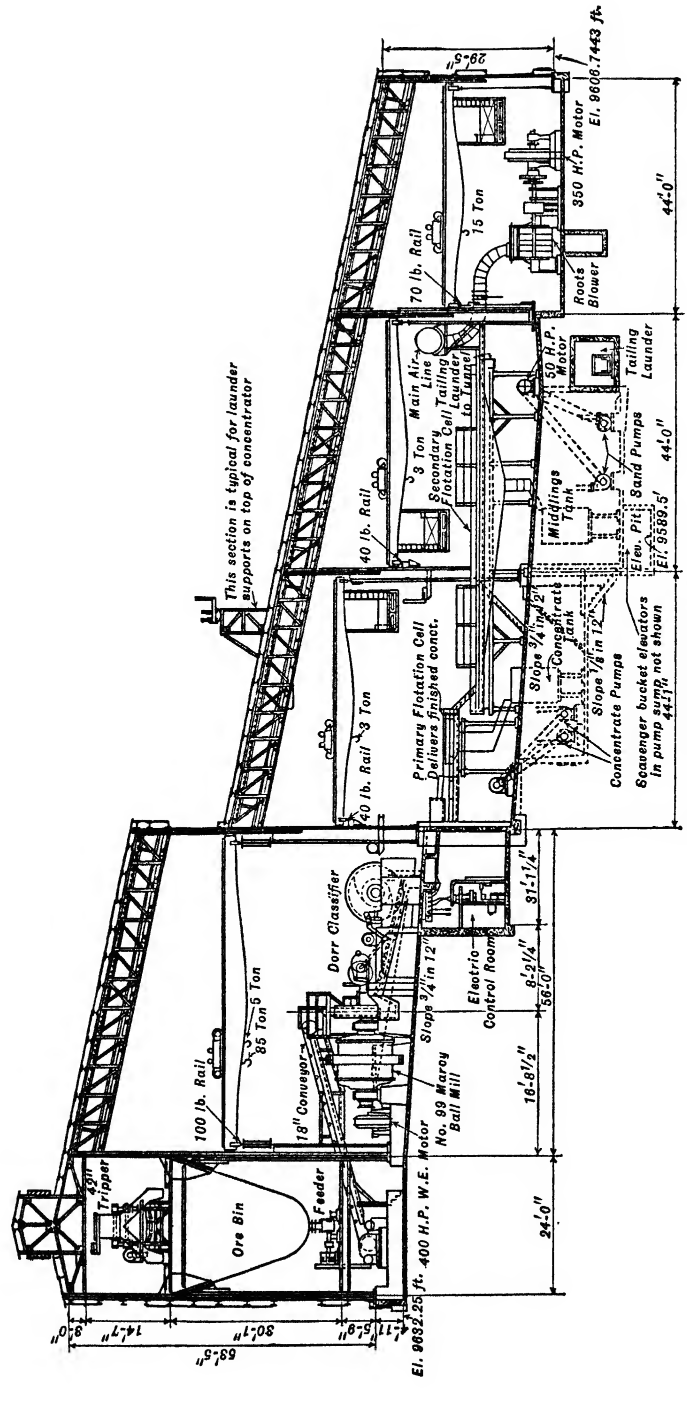

Fig. 13. Mill building at Andes.

Power: Three sources: Steam-power station at Barquito, transmitted 79 mi. at 88,000 volts; hydroelectric station at Montandon, transmitted 9.6 mi. at 13,000 volts; waste-heat steam plant at smelter. Motors 50-hp. and up, 2,200-volt, 60-cycle; below 50-hp., 440-volt, 60-cycle. CONSUMPTION: See Table 14.

Transportation: Railroad trackage serves entire plant. Ore, 6.2 mi.; concentrate, 270 ft. by conveyor to roaster plant.

Tailing disposal: 7,500 ft. by launder to pond. Dam is built up in terraces by sand spigot product from dewatering cones carried on a bolted wooden trestle of standard sections. Trestle is dismantled and moved for each 16-ft. lift of dam crest. Cone overflow is deposited behind dam, the coarser delta deposit adding thereto. Water drains through a tunnel at far end of pond. When water reclamation is desirable, tailing on the way to the pond is passed through a 200-ft. thickener, traction-type, located alongside the tailing launder about 1,750 ft. from the concentrator.

Summary. Run-of-mine (<16-in.) to <1 1/2-in. ball-mill feed in two steps by three relatively small gyratories in parallel and 48 vertical disk crushers in parallel in open circuit; grinding to 48-*mog* (54% <200-m.) flotation feed in one stage; all-flotation concentration by a rougher-scavenger flow with one-stage cleaning of scavenger concentrate and counterflow of cleaner tailing to the scavenger cell.

This plant was built just prior to the appearance of the cone crusher, and represents a crushing-grinding flowsheet that was hotly supported by one school at that time. There can be no doubt but that present-day design would replace the disk crushers with a much smaller number of cones or similar crushers; many designers would interpose fine crushers to perform much of the size reduction from 1 1/2-in. to 1/8- or 3/8-in., with corresponding relief of the ball mills.

Recovery of sulphide copper is surprisingly high considering the coarse feed to flotation. This is due to the relatively high insoluble and iron contents permitted in the concentrate.

Minas de Matahambre, S. A. Fig. 14 (*Q* by D. D. Homer, Gen'l M'g'r; John M. Brooks, Jr., Ass't Gen'l M'g'r; H. D. Bemis, Concentrator Sup't; *IC 6544*).

Location: Matahambre, Piñar del Rio, Cuba.
Ore: Chalcopyrite and pyrite in shale and quartzite.
Capacity: 1,200 tons per 24 hr.
Assays: See Table 16.
Recovery: 95.8%.
Ratio of concentration: 6.3 : 1.
Labor: Cuban, foreign. Tons per man-shift, total, 18.
Running time: 81%. Principal loss due to holidays and social laws.
Water: Sources, river and mine. Pumped 500 ft. at consumption of 70 hp. About 10% re-used. Net consumption, 2 tons per ton of ore.
Building: Wood, with wood and concrete floors sloping 1/16 in. per ft. in wet part of mill. Unheated. Sloping site.
Machinery handling: Power crane and chain blocks in crushing and grinding sections; hand chain blocks in concentrator.
Power: Steam-turbine generators at Santa Lucia. Transmitted 5 mi. at 110,000 volts. Motors 110-, 440-, and 2,200-volt, 60-cycle. Consumption, 23.4 hp-hr. per ton milled.
Transportation: 25 mi. to nearest railroad, 9 mi. to seaport at Santa Lucia. Crushing plant at shaft; 800 ft. to mill bins by rope tram. 1,200 mi. to smelter.
Tailing: See flowsheet, note (19).
Costs: (1936) Crushing, $0.11 per ton; total, $0.48 per ton milled.

concentration, with pyrite rejection; rougher-scavenger routing with two cleanings, and counterflow of all middling to the rougher.

Mountain City Copper Co. Fig. 15 (*Q* by John C. Lokken, Concentrator Sup't).

Location: Rio Tinto, Nev.

Ore: Chalcocite, 3.5 to 3.6%; chalcopyrite, 15 to 16.5; pyrite, 15 to 20.5; quartz and carbonaceous shale, 53 to 58%.

Capacity: 475 tons per 24 hr. max.

Assays: Feed: Cu total, 8.6%; Cu oxide, 0.37; Fe, 12.8; insol., 57.7; Au, 0.005 oz. per ton; Ag, 0.20 oz.; concentrate; 25.9% Cu; tailing, 0.58% Cu.

Recovery: 95.7% Cu.

Ratio of concentration: 3.2 : 1.

Labor: American. Tons per man-shift: operating, 30; repairs, 150.

Running time: 98.8%. Inspection and repairs principal causes of delay.

Water: Mine water pumped 1/10 mi. at consumption of 7.5 hp., 78% of water re-used. Net CONSUMPTION, 1.25 tons per ton of ore.

Building: Steel frame; roof insulated and copper covered; sides, corrugated galvanized iron; floors, concrete, steel, and wood sloping 1 1/4 in. per ft. in ball-mill section and 1/4 in. per ft. under flotation slat floor. Heated. Sloping site.

Machinery handling: Hand chain-block hoists.

Power: Purchased; comes 100 mi. at 44,000 volts; motors, 2,200- and 440-volt, 60-cycle. 28.7 hp-hr. per ton milled.

Transportation: Nearest railroad, 90 mi. Ore by conveyor 300 ft. from mine to mill after primary crushing; concentrate shipped to railroad by motor truck, thence 230 mi. by rail to smelter.
Tailing: To pond behind earth dam. Overflow clear.

Fig. 15. Mountain City Copper Co.

Summary. Crushing from <14-in. to <1/2-in. in two stages (jaw crusher and cone). One-stage ball-mill grinding in closed circuit to flotation feed. All-flotation concentration, rougher-scavenger routing, two-stage cleaning, counterflow of all middling to the rougher.

Magma Copper Co. Fig. 16 (*Q* by J. C. McNabb, Ass't Mill Sup't).

Location: Superior, Ariz.
Ore: Chalcopyrite, bornite, and pyrite in quartz and diabase.
Capacity: 750 tons per 24 hr.
Assays: See Table 18.
Recovery: 96.6%.
Ratio of concentration: 2.64 : 1.
Labor: American, 2/3; Mexican, 1/3. Tons per man-shift: Operating, 50; repairs, 55.4; total, 15.6.
Running time: 83.5%. Principal causes of loss: Grinding-mill repairs, elevator repairs and inspection, summer shutdown of one month to 6 weeks.
Water: Mine water, 1/2 mi. by gravity. 75% re-used. Gross consumption, 4 to 5 tons per ton of ore; net, 1.25 tons.
Building: Timber frame, corrugated-iron covering, wood and concrete floors. Unheated. Sloping site.
Machinery handling: Chain blocks.
Power: Smelter waste-heat boilers supplemented by purchased power coming over 70-mi. line at 110,000 volts. Motors: 2,300-, 440-, and 110-volt, 25-cycle. Consumption: 27.5 hp-hr. per ton milled.
Transportation: Spur on property. Ore hauled 1/2 mi. in trains of 12 @ 3 1/2-ton side-dump cars; concentrate pumped (30% moisture) 1/2 mi. to filter plant at smelter.
Tailing: Lifted by pump to 10×12-in. launder on high bents running around 3 sides of tailing pond; 3×4-in. distributing launders spaced 10 ft., fed from holes in bottom of main launder, carry pulp to building dam. Two men required.
Cost (1929): 93¢ per ton total, of which crushing was 8¢, grinding 30¢, and flotation 17¢. (*IC 6319.*)

FIG. 16. MAGMA COPPER CO.

Summary. Crushing from run-of-mine (head-size) to <3/4-in. ball-mill feed in two stages by jaw crusher and cone in open circuit. Grinding to 65 *mog*, 57% <200-m., in two ball-mill stages, the primary closed with traveling-belt screens, the second by drag classifiers. Concentration comprises gravity scalping of concentrate from primary ball-mill discharge, and bulk flotation of a high-iron low-silica concentrate by a simple rougher-scavenger flow.

The simplicity of this flowsheet is justified by the fact that the smelter receives much siliceous gold ore and needs iron for fluxing. Hence low-grade table concentrate is acceptable and nearly 20% of the mill feed can thus be taken out of the secondary ball-mill and flotation circuits.

Mufulira Copper Mines, Ltd. Fig. 17 (*Q* by Frank Ayer, Gen'l M'g'r, and Jack Ong, Concentrator Sup't).

Location: Mufulira, No. Rhodesia.
Ore: Copper sulphides (chalcocite, bornite, chalcopyrite) and oxides (malachite, azurite, chrysocolla, tenorite, cuprite, native copper) in a highly silicified quartzite containing some weathered feldspar.
Capacity: 8,000 tons per 24 hr.
Assays: See Table 19.
Recovery: Sulphide, 93.8%; total, 86.2%.
Ratio of concentration: 14 : 1.
Labor: 180 tons per man-shift (European), 28 (native), operating; 599 tons per man-shift (European), 178 (native), repairs.
Water: 1.5 to 2 tons per ton of ore net CONSUMPTION; about 80% re-used. Sources are mine and river, distant 1/4 and 3 mi. respectively.
Percentage possible running time: 60 to 80; principal cause of lost time is quota restriction.
Building: Steel, level site; wood and concrete floors, 1/2 in. per ft. slope in concentrator. Unheated.
Machinery handling: Power cranes throughout.
Power: Local station generating at 3,300 volts, 50 cycles; transmission, 1/2 mi. at 3,300 volts; motors, 3,300- and 550-volt; CONSUMPTION, 19.8 kw-hr. per ton ore milled.

Summary. Crushing from <20-in. r.o.m. to <3/8-in. ball-mill feed by gyratory and a 2-stage cone series; grinding to 65-*mog* flotation feed in a simple one-stage ball mill-classifier circuit; all-flotation concentration, comprising a primary rougher and 2-stage scavenger circuit with intermediate dewatering, and 2-step cleaning; regrind of all middling with a scalping cell in the circuit preceding the classifier and sending concentrate to

the primary cleaner; return of scalped reground middling to the rougher. No special attempt is made to recover the relatively high percentage of oxide copper (0.5%) and the extraction thereon is less than 25%.

Utah Copper Co. Fig. 18 (*Q* by Staff).

Location: Garfield, Utah.

Ore: Chalcopyrite, bornite, chalcocite, covellite, malachite, azurite, chrysocolla, 2.5% (the chalcopyrite comprising about 75% of the total of copper minerals), pyrite, 2.5% (pyrite is barren of copper, if fine enough); feldspar, 35%; quartz, 30; micas, 20 to 25; chlorite, talc, rutile, apatite, etc., 5 to 10; molybdenite, trace. Fine dissemination.

Capacity: Magna plant, 33,766 tons per 24 hr. (aver. 1937); Arthur plant, 30,815 tons per 24 hr. (aver. 1937). These two plants are treating 100,000 t.p.d. in 1944 without increase in equipment and with little sacrifice in recovery.

Assays: (Magna plant, 1937; Arthur plant substantially the same.) Feed, 0.9761% Cu; concentrate, 34.772; tailing, 0.096.

Recovery: 90.45%.

Ratio of concentration: 39.4 : 1.

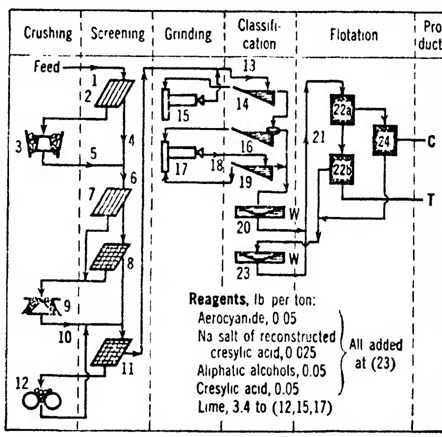
Water: By canal 35 mi. from Utah Lake; also from local wells and drainage canals. CONSUMPTION, 2.54 tons per ton milled; 33% of total reclaimed.

Power: Purchased; comes 140 mi. at 130,000 volts; motors 440- and 230-volt, 60-cycle. CONSUMPTION, 16.9 hp-hr. per ton milled.

Mill building: Sloping site. Steel frame, corrugated galvanized-iron covering; concrete floors. Unheated. Machinery handled by power cranes.

Transport: Mine to mill, 17 mi. by standard-gage gondola cars; mill to smelter, 3 1/2 mi. by standard-gage gondola cars; 9.65% moisture in concentrate.

Costs (1930): Crushing to 8-m., 6¢ per ton; grinding to 48-*mog*, 9¢; flotation, 9¢. Total operating cost, about 30¢ per ton, divided: labor 8¢, power 11¢, supplies about 10¢ (*IC 6479*).



Legend for Fig. 18:

FIG. 18. UTAH COPPER CO.

Summary. Three-stage crushing from steam-shovel size to 6-m. ball-mill feed 2-stage grinding to 65 *mog* for flotation. All-flotation concentration with rougher-scavenger flow on the primary stream and one-stage cleaning.

Nevada Consolidated Copper Corp., Hayden division, Fig. 19 (*Q, IC 6241*).

Location: Ray, Ariz.
Ore: Chalcocite and pyrite in quartz-sericite schist.
Capacity: 12,000 tons per 24 hr.
Assays, % Cu: Feed, 1.5; concentrate, 20.0; tailing, 0.16 to 0.18.
Recovery: 85 to 90%.
Ratio of concentration: 15 or 16 : 1.
Water pumped 1.5 mi. from Gila River with a consumption of 700 to 800 hp. Net CONSUMPTION, 2.5 to 3.0 tons per ton of ore; water from concentrate only re-used.
Power is company generated, using coal or oil for fuel; transmitted 1/4 mi. at 6,600 volts. Motors, 440-volt, 60-cycle. CONSUMPTION, 13.5 hp-hr. per ton milled.
Mill building: Sloping site. Steel frame, galvanized-iron covering. Concrete floors: slope in wet part, 1/2 in. per ft. Unheated.
Machinery handling: Power cranes throughout.
Transport: 26-mi. mine to mill via standard-gage railroad and 60-ton cars. Concentrate shipped 1/2 mi. in railroad cars at 12% moisture.
Running time: 99%. Lost time due to charging rods.
Cost (1928)*:* 40¢ per ton total, of which 11¢ was crushing, 8¢ grinding, and 9¢ flotation; distribution was labor 10¢, supplies 14¢, power 10¢, miscellaneous 5¢ (*IC 6241*).

FIG. 19. NEVADA CONSOLIDATED COPPER CO., Hayden division (RAY).

Summary. Two-stage crushing from <16- or 18-in. r.o.m. to <1-in.; open-circuit rod mill to 19% >14-m.; 1-stage closed-circuit ball mills to 48 *mog* for flotation feed; all-flotation concentration with rougher-scavenger flow on the primary stream and one cleaning.

Phelps Dodge Corp., New Cornelia plant. Fig. 20 (*Q* by H. M. Lavender, Gen'l M'g'r; *141 #9 J44; 134 A 434*).

Location: Ajo, Ariz.

Ore: Chalcocite, bornite, and chalcopyrite in siliceous monzonite porphyry; traces of hematite, magnetite, molybdenite, pyrite, sphalerite, and tennantite.

Capacity: 20,000 tons per 24 hr.

Assays: Feed, 0.93% Cu, including 0.01% oxide Cu; Ag, 0.074 oz., Au, 0.0057 oz.; concentrate, 31.3% Cu, 2.19 oz. Ag, 0.16 oz. Au, 24.5% Fe, 28% S, 13% SiO_2, 2.3% Al_2O_3; tailing, 0.08% sulphide Cu, 0.01% oxide Cu, 3.0% Fe, 0.24% S, 67% SiO_2, 16% Al_2O_3.

Recovery: 92% sulphide copper, 85% Ag, 80% Au.

Ratio of concentration: 37 : 1.

Labor: Mostly American, some Mexican and Indian; 98 tons per man-shift, operating; 144 tons per man-shift, repairs.

Water: 4 tons per ton milled; 0.92 ton per ton net CONSUMPTION. Source, wells 7 mi. distant; pumped to mill through 20-in. steel line; lift 1,160 ft., 6,500,000-gal. storage reservoirs at plant.

Table 20. Power consumption at New Cornelia

	Kw-hr. per ton
Crushing plant	2.79
Grinding	7.58
Flotation	1.42
Concentrate handling	0.12
Tailing disposal	0.28
Reclaimed water	0.89
Concentrate regrinding	0.44
Lighting (mill)	0.07
Miscellaneous (mill)	0.06
Total, exclusive of new water	13.65

Percentage possible running time: 98; general repairs principal cause of lost time.

Building: Steel and concrete, sloping site; concrete floors sloping 1/8 in. per ft. in wet part of mill. Unheated.

Dust control: Ore sprayed at shovel and during loading, dumping, and at numerous points in circuit. A low-pressure exhaust system with wet collection connects with housed-in conveyor-loading and transfer points, screen feeders, screens, screen-feed, and short-head feed bins. Conveyor belts are vacuum cleaned before starting the return run and dust accumulations on the crushing-plant structure are removed by vacuum as a routine procedure.

Machinery handling: Power cranes throughout.

Power: Local steam power plant generating at 2,300 volts, 60 cycles; transmission, 2,000 ft. at 2,300 volts; motors, 2,300- (25-hp. and up) and 440-volt; extensive use of synchronous-type to maintain high power factor; CONSUMPTION, see Table 20.

Transportation: Spur into plant; ore, 1 mi. in 40- to 65-ton side-dump cars; concentrate, 295 mi., 7.3% moisture.

Steel consumption: Crushing plant, total, 0.081 lb. per ton.

Costs: Crushing, $0.088 per ton of mill feed; grinding, 0.098; flotation, 0.042, concentrate retreatment, 0.006; concentrate handling, 0.009; tailing disposal, 0.013; mill water, 0.029; miscellaneous, 0.023; total, $0.308; distributed as follows: labor, $0.088 per ton of feed; supplies, 0.116; power, 0.074; fresh water, 0.013; miscellaneous, 0.017.

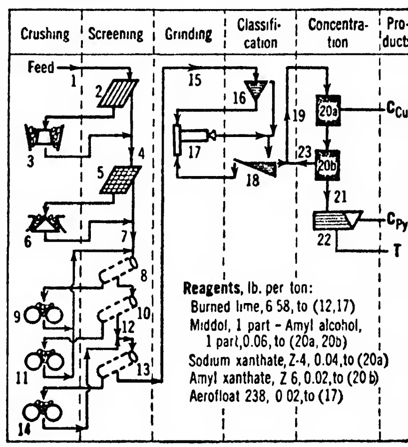
a For chalcopyrite ores; chalcocite ores require grinding to about 6% >65-m.

Summary. Crushing from steam-shovel size to <$^5/_{16}$-in. ball-mill feed by a 2-stage gyratory and 2-stage cone series; grinding to 48 *mog* for flotation feed in a 2-stage ball mill-classifier circuit with partial closure on the first stage; all-flotation concentration with one-stage roughing at 48 *mog*, light cleaning, regrind of primary cleaner tailing, and a rougher-scavenger flow on this product to make tailing, with one cleaning of regrind concentrate.

Anaconda Copper Mining Co., Fig. 21 (*Q* by Thomas Morris).

Location: Anaconda, Mont.
Ore: Bornite, chalcocite, chalcopyrite, and pyrite coarsely disseminated in granitic gangue.
Capacity: 2,000 tons per section per 24 hr. 8 sections substantially alike. Average daily mill tonnage of copper ore, 15,000.
Assays and recovery: See Table 22.
Ratio of concentration: Cu, 5.96 : 1.
Distances: Mines at Butte, 32 mi. distant by standard-gage railroad; smelter at mill.
Tailing: Flows by gravity about $^1/_2$ mi. to pond on flat below mill.



Legend for Fig. 21:

1. 50-ton standard-gage cars 32 mi. from Butte; 1 @ 40-ft. rotary car-dump, 75-hp. motor, capacity 1,200 tons per hr.; 200-ton (live capacity) bin; 1 @ 54-in. pan feeder, 20 to 40 f.p.m., 15-hp. variable-speed motor; 1 @ 60-in. belt conveyor, 132 f.p.m., 75-hp. motor, wood picked and sent to 50-ton cars via 24-in. belt conveyor; hopper.
2. Grizzly, 3 $^1/_2$-in. spacing (one spare).
3. 2 @ 20-in. gyratory crushers, 3-in. closed setting, 225-hp. motor.

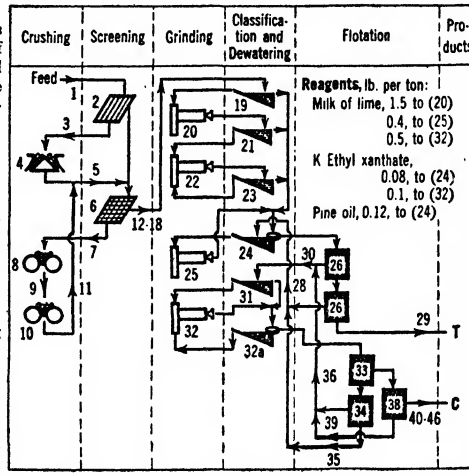
Transportation: Railroad on property. Crushing plant at shaft. Mill ore, 1,200 ft. by belt conveyors. Concentrate shipped 2 mi. by rail to smelter.
Tailing disposal: See Sec. 20, Art. 3.

Summary. Crushing from <10-in. r.o.m. to <3/8-in. ball-mill feed in primary cones followed by two rolls in series, the second rolls in the series in closed circuit with a screen battery. Grinding to 35 *mog*, 51% <200-m. flotation feed in ball mills in three stages, with four stages of classification of which the third closes the circuit on the second grinding stage and the fourth (bowl) both closes on the third grinding stage and finishes the overflows of the preceding three stages of rake classification. All-flotation concentration in a rougher-scavenger primary circuit, 2-stage cleaning after regrind, with rich middling counterflowed to the regrind circuit, and low-grade middling to the third stage of the primary-grinding circuit. Lime only, and that in relatively small quantity, added in

steps, is used for depressing pyrite; a greater quantity depresses chalcocite. An exceptionally high grade of concentrate is made and the recovery of sulphide copper is remarkable



Legend for Fig. 22:

1. The following, down to item 16, is one of three similar units fed at the rate of 550 tons per hr. each. Mine run ore, all through 10-in. grizzly underground (some sledging necessary), to 1 @ 1,400-ton circular steel bin, pan feeder.

2. Cantilever grizzly, 4(wide)×5 1/2 ft., 1-in spacing.

3. Table 25.

4. 1 @ 7-ft. cone crusher, set 5/8 in.

5. Conveyor (Table 25); surge bin, 5 roller feeders.

6. 5 vibrating screens (one Traylor, 4 @ 66×72-in. Mitchell), 5/16-in. (top half) and 3/8-in. (bottom half) sq. aperture.

7. Table 25.

8. 77×24-in. A-C rolls, set, according to hardness of ore, to crush to 5/8-in., 125 r.p.m.; 400-hp. motor; 0.41 kw-hr. per ton.

9. Table 25.

10. 80×24-in. Traylor rolls, set, according to hardness of ore, to crush to 1/4-in , choke-feed, 160 r.p.m.; 300-hp. motor; 0.68 kw-hr. per ton. Speed of these rolls was increased to the figures given to take care of larger tonnages without appreciable increase in repair costs.

considering the grade of feed. Owing to relatively coarse primary grinding, rejection of better than 90% of the mill feed at this size, and the use of exceptionally large machines, with corresponding economies both in operation and carrying charges, milling costs are kept down to about 26¢ per ton milled.

Table 26. Flotation operating data at Miami

Machine			Tons solid per machine per hr.	Air		Kw-hr. per ton	Time-factor, min.	Pulp			Assays	Attendance

g New feed. Circulating load roughly doubles this.

Nevada Consol. Copper Corp., Chino division. Fig. 23 (*Q; 140 # 9 J 29*).

Location: Hurley, N. M.

Ore: Chalcocite as small stringers and veinlets and as scattered grains in highly metamorphosed quartz-diorite porphyry and sedimentaries. In some parts of the mine azurite, malachite, chrysocolla, and cuprite accompany the chalcocite. The principal gangue minerals are quartz, pyrite, sericite, and halloysite.

Capacity: 17,500 tons per 24 hr.

Assays: Feed (aver.) 1.24% Cu, 2.96% Fe; Cu concentrate (aver.), 27.8% Cu, 27.6% Fe, 4.3% insol.; MoS_2 concentrate, 85% MoS_2, 0.80% Cu, 3% insol.; tailing, 0.22% Cu.

Recovery: (1938) 80.7%.

Ratio of concentration: Cu, 31.2 : 1.

Running time: 99.1%; principal delay due to repairing and charging rod and ball mills in primary grinding.

Power: Steam-power plant at millsite, using coal and gas as fuel; 440-volt 60-cycle motors; CONSUMPTION, 18.6 hp-hr. per ton of ore milled, distributed substantially as follows: crushing, 14%; grinding, 55%; flotation, 11%; dewatering, 2.0%; water supply, 18%. Crusher plant is controlled from an observation booth located between the car-dump and the jaw crusher.

Water comes 4 mi. from deep wells through 20-in. line, 224 hp.; CONSUMPTION, 3.3 tons gross per ton of ore milled; 70% reclaimed.

Mill building: Sloping millsite. Building, steel and concrete, corrugated-iron enclosure; concrete floors sloping 1/2 in. per ft. in wet section. Unheated.

Machinery handling: By power cranes throughout.

Tailing disposal: By gravity 6,590 ft. by 30-in. wood-stave pipe at slope of 4.7 ft. per 1,000; a cylindrical concrete distributor box feeds through 20-in. wood-stave lines and launders to different parts of the tailing pond. (See also *IC 6394*.)

Distances: Mine to mill 9 mi.; ore comes in 80-ton gondola cars by A.T. & S.F.R.R.; smelter at concentrator.

Summary. Three-stage crushing in jaw crusher, cone and closed-circuit rolls from steam-shovel size to 1/4-in.; two (or three) -stage grinding in open-circuit rod mills and closed-circuit ball mills to 3% > 48-m. flotation feed; rougher concentrate reground before cleaning. All-flotation concentration, with rougher-scavenger primary flow, regrind of rough concentrate before cleaning.

Phelps Dodge Corp., Morenci plant. Fig. 24 (*23 MMt 258*).

Location: Morenci, Ariz.

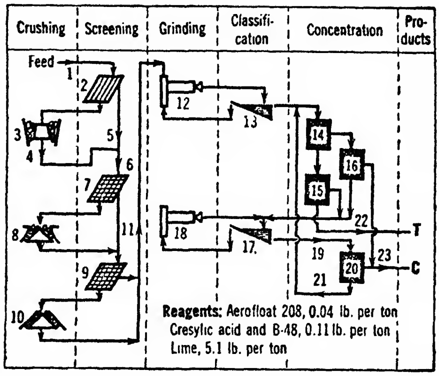
Ore: Porphyry; chalcocite and pyrite with some covellite; much clay. Open-pit mining with 4 1/2-cyd. shovels.

Capacity: 27,000 tons per 24 hr. Being enlarged to 45,000 to 50,000 tons capacity (1943).

Assays: Feed, 1% Cu aver.; it is planned to send rock containing 0.5% Cu to the mill. Concentrate (based on 1-yr. large-scale pilot-plant work), 21.2% Cu, 29.4% Fe, 38.3% S, 9.4% insol. Tailing, 0.15% Cu.

Recovery: 85.9% (92.6% sulphide).
Ratio of concentration: 24.3 : 1.
Water: 4 tons per ton of feed; about 80% reclaimed.

Legend for Fig. 24:



1. 80-ton side-dump cars in 11-car trains with 125-ton (1,325-hp.) trolley-battery electric locomotives from pit, 3 mi. average haul. Normal dump interval 1.4 min.; have operated on 1.04 min. interval. Feed runs as coarse as 6- to 8-ft. in one dimension.

2. Grizzly (Fig. 26, item *d*); stationary, heavy I-beams capped with manganese-steel castings; slope 40°±slight adjustment; spacing increases to 9-in. along the run. About 60% oversize with normal blasting.

3. 1 @ 60-in. gyratory, short-shaft suspended-spindle double-discharge type (Fig. 26, item *g*). 500-hp. @ 265-r.p.m. motor direct-connected through a tear coupling with rubber-fabric disk. Forced-feed lubrication to the eccentric and main step bearings with overflow to bevel gears and pinion-shaft bearings; circulation through a cooling tower; separate noncirculating mechanical oil feed to the suspension bearing. Remote start-and-stop control from the car-dumping platform, with signal lights from transport equipment up to the primary-storage bin (Fig. 27, item *m*).

4. 190-ton surge pocket (Fig. 26, item *h*).

5. 300-ton surge pocket (Fig. 26, item *e*).

6. 2 @ 72-in.×38-ft. manganese-steel apron feeders in parallel (Fig. 26, item *j*); variable-speed d.-c. motors direct-connected through triple-reduction herringbone gearbox; electrically interlocked with the following conveyor; capacity at 39 f.p.m. with 42-in. depth of load (controlled by hinged leveling weights), 2,250 t.p.h. 2 @ 54-in.× 700-ft. belt conveyors in parallel (Fig. 26, item *i*), lift 125 ft. at 15°, vertical radius 350 ft., 425 f.p.m., 2,300 t.p.h. max. capacity at safe tension. 1 @ 13,000-ton steel suspension bunker. 8 @ 48-in. apron feeders. 2 @ 60-in. gathering conveyors in parallel; run at 200 f.p.m. to permit hand picking of wood and nonmagnetic steel. Mushroom magnets over the belts, and magnetic head pulleys.

7. 2 @ 6×14-ft. Ty-rock screens with cross-rod (1 1/4-in. diam.) surface, 3-in. spacing, 20 1/2° slope.

8. 2 @ 7-ft. standard cone crushers in parallel; set 2 1/2 in.

9. 4 @ 5×10-ft. Ty-rock rod-deck screens; transverse rod, 3/4-in. spacing.

10. 4 @ 7-ft. short-head cone crushers, set 5/8-in.

11. 2 @ 54-in. gathering conveyors; 1 @ 54-in. transfer conveyor; 1 @ 54-in.×800-ft. conveyor, 75-ft. lift at 20° slope, 475 f.p.m., with traveling tripper (max. safe capacity, >2,500 t.p.h.). 1 @ 16,000-ton (live) steel-plate suspension bunker, 448 ft. long, flat rack-and-pinion cutoff gates, 4 for each ball mill (item 12). 16 @ 36-in. short gathering belt conveyors parallel to bin axis, with variable-speed d.-c. motors; delivering to 16 @ 24-in. ball-mill feed conveyors at constant speed, with weightometers actuating motor-driven rheostats on the line to the variable-speed motors on the preceding gathering conveyors.

12. 16 @ 10×10-ft. grate ball mills (10 ft. 2 in. diam.×10 ft. 5 in. inside liners), 17.9 r.p.m., 800-hp. synchronous motors, 50-ton ball charge. Special discharge trunnion has 4 spiral passages; alternate spirals discharge by ports in the trunnion to one launder and by the normal lip to a second.

13. 32 @ 56-in. duplex submerged-spiral Akins classifiers (2 in parallel per mill). Overflow, 65 *mog*; pulp density, 17% solids, is dictated by classification requirements.

14. 80 @ 66-in. Fagergren square-type roughing flotation cells in 20 parallel level-bottom rows of 4 cells ea. Thickening feed to 25% solids gave only 20% increase in capacity despite an increase in time-factor of roughly 30%; further thickening to 33% solids lowered concentrate grade without improving recovery.

15. 160 @ 66-in. Fagergren square-type scavenging flotation cells in 20 parallel level-bottom rows of 8 cells ea.

16. 52 @ 56-in. Fagergren square-type primary cleaner cells in 4 @ 4- and 12 @ 3-cell parallel level-bottom rows.

17. 3 @ 54-in. duplex submerged-spiral Akins classifiers.

18. 3 @ 8 1/2×12-ft. ball mills.

19. 6 @ 8-in. Wilfley pumps.

20. 40 @ 56-in. Fagergren square-type secondary cleaner cells in 8 @ 3- and 8 @ 2-cell parallel level-bottom rows.

21. 8-in. sand pumps.

22. Main tailing launder, slope 3/8-in. per ft.; 8(deep)×12×13-ft. distributing box; 4 @ 300-ft. traction-type thickeners; overflow to a 1,000,000-gal. sump and thence by 4 of 5 @ 5,000-g.p.m. centrifugal pumps to main supply tanks; spigot products by 3 @ 8-in. pipes from each thickener all to a head box; tailing sampler; tailing launder (54 in. wide at top, 21 1/2 in. deep, U-shaped with slanting sides, 16,000 ft. long, 2% grade); 4 distributing pipes on trestles, discharging through 6-in. plug valves at 54-in. intervals to 4 tailing dams with chimney weirs; 6 collector pumps; 50,000-gal. equalizing tank; 3 @ 1,000-g.p.m. centrifugal pumps to the above million-gallon sump.

23. 2 @ 100-ft. thickeners; water to head tanks; spigot to bucket elevator to 4 @ 7-leaf 8 1/2-ft. disk-type filters; cake to belt conveyor to concentrate beds at smelter.

Fig. 24. Phelps Dodge Corp., Morenci plant.

Plant

The plant, shown in plan in Fig. 25, comprises the crushing and concentrating unit, the smelter, the tailing-disposal and water-recovery system, and the power plant. The site was graded to permit

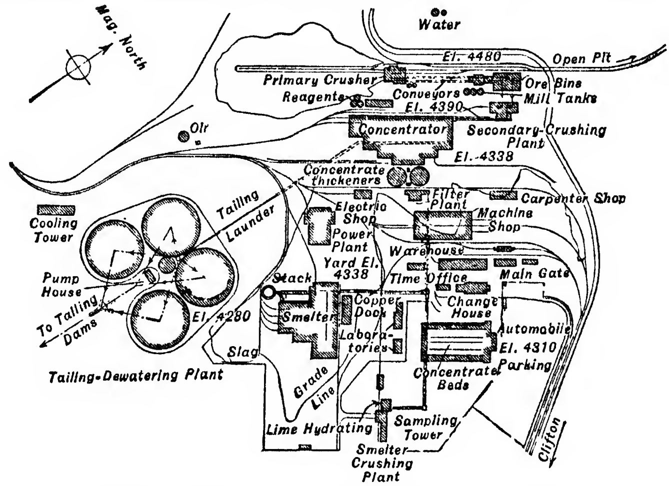


FIG. 25. Plan of milling and smelting plant at MORENCI.

parallel placing of the long axis of buildings as shown, with a drop of about 140 ft. from the feed floor of the primary crusher to the bottom floor of the concentrator, which is also the level of the yard, the smelter, and the power plant.

Primary-crusher house (Fig. 26) comprises a steel and concrete structure 73 ft. wide, 110 ft. long, and about 150 ft. from eaves to lowest floor, of which about 100 ft. is below the feed floor. Ore cars *a* dump into pocket *b*, lined on sides and back with rail set close and bolted to the walls, and protected on the bottom by the dead load. The ore, at diminished velocity, slides over grizzly *d*. Undersize falls into pocket *e*, 317 tons live capacity, protected against wall wear by the 30-in. shelves *f*, which are tipped with manganese-steel angles upturned to hold a bed and take the edge wear on the shelves. Grizzly oversize, crushed in the gyratory, falls into 190-ton (live) surge pocket *h*. Simultaneous discharge from *e* and *h* is into the ends of 2 @ $8 \times 5\ 1/2$-ft. bottom gates *i* onto 2 parallel 72-in. $\times 38$-ft. feeders *j* and thence into one or both feed boxes *k* which feed over grizzlies (not shown) onto belts *l*, which transfer to bin *m*, Fig. 27. For further detail of the various apparatus see items 1 to 6, Fig. 24.

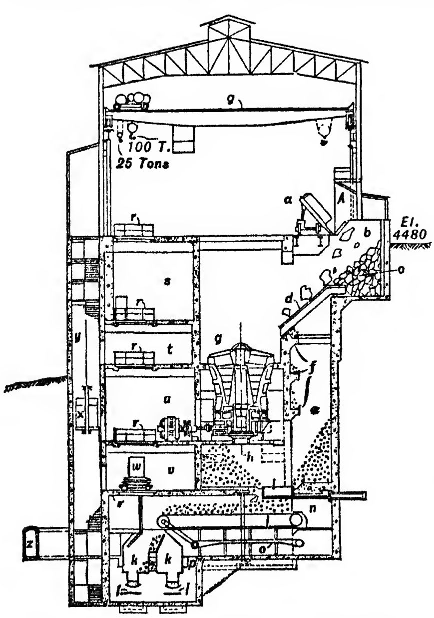

FIG. 26. Primary-crusher house at MORENCI.

Provision has been made for installation of a Ross chain curtain between *b* and *d*, if this appears desirable to prevent excessive bounding.

The drop from the lower end of *d* to the level of the gyratory hopper is such that the minimum slope for the furthest horizontal travel is 45°.

The combined live capacity of *e* and *h*, on the basis of a 60 : 40 split between oversize and undersize in run-of-mine is about 320 tons. With a feed rate during unloading of 3,430 t.p.h. (see Fig. 24, item 1) and 2-shift operation for 27,000 t.p.d. (1,700 t.p.h.), this surge capacity at best spreads the load 320/3,430 = 9.3%, *i.e.*, the normal hourly load comes in in about 21 min. and must be taken away in 23 min. Hence these pockets are essentially nothing more than ore-lined chutes to take impact from feeders *j*.

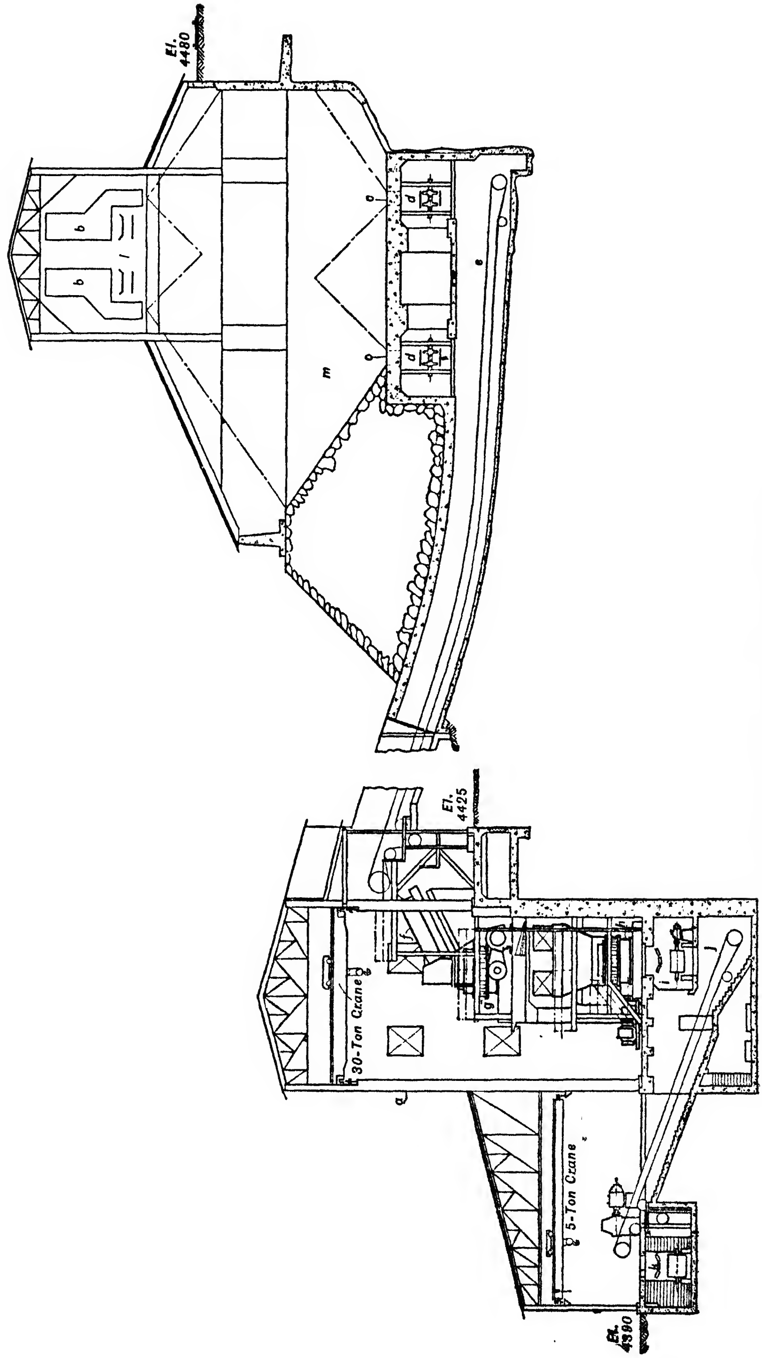

FIG. 27. Secondary-crushing plant at MORENCI.

Exit *i* is placed well over toward pocket *e* so that ore must hang up in *e* on a slope greater than 75° before flow through *e* ceases; with a mean fall of about 35 ft. from *d* to the pile in *e*, it is unlikely that <9-in. ore will stand on a steeper slope than this. Gate *n* is hydraulically operated, with an available push of 50,000 lb. total.

Item *o* is 2 parallel 54-in. belt conveyors to take spill from the return run of feeders *j* and deliver via chutes *p* onto conveyor *l*.

Crane *g* has a slow-speed 100-ton hook and a higher-speed 25-ton hook. It is directly available to the gyratory, both for maintenance and to handle the jam hook; the track section over the grizzly is

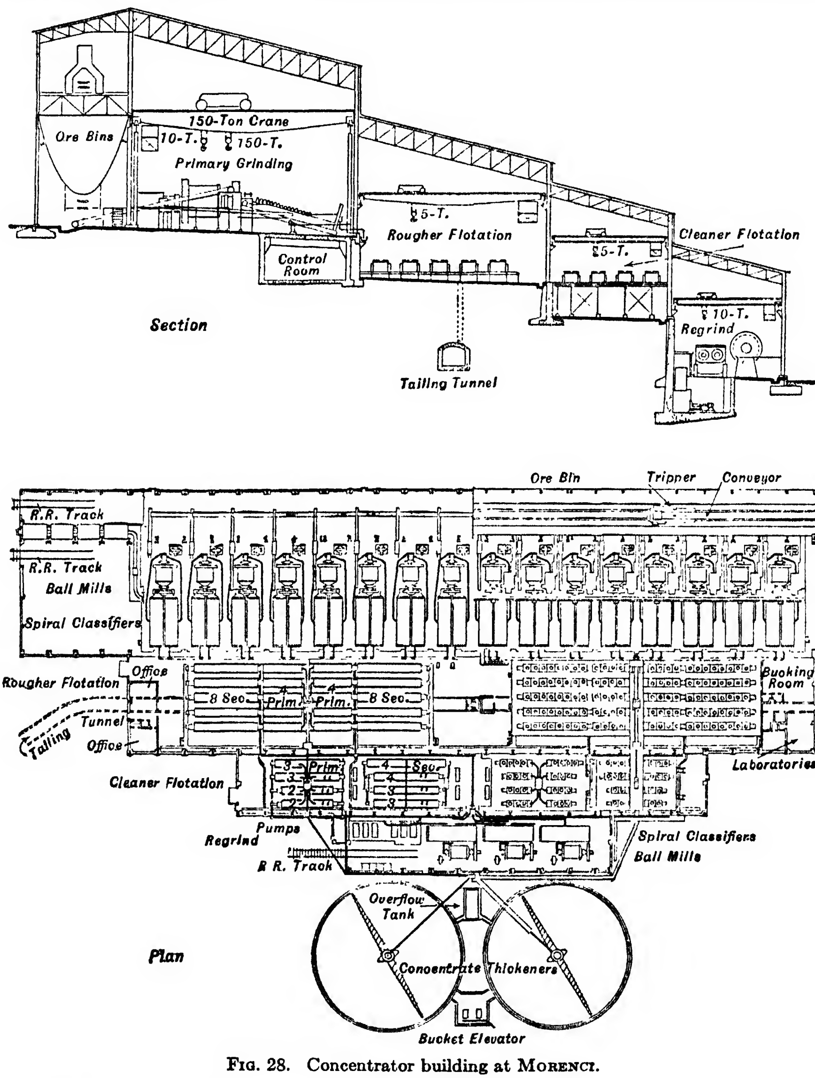

FIG. 28. Concentrator building at MORENCI.

removable, so that the crane can serve the grizzly; finally, through hatches *r*, it serves in succession the air-conditioned belt-storage room *s*, fan room *t*, motor room *u*, room *v* entered by car *w* on which the bottom plate of the gyratory may be lowered, and finally the feeder floor. Elevator *x*, serving rooms *t*, *u*, and *v*, is 10-ton capacity. A service track enters the building alongside the ore track.

Stair-well *y* and tunnel *z* give access to the structure from feed floor and secondary-crushing plant respectively.

Secondary-crushing plant (Fig. 27) consists of the primary storage bin *m* and the steel and concrete building *a* with the enclosed machines. Conveyors *l* from the primary plant (Fig. 26)

discharge via trippers *b* into bin *m*, and ore passes thence by 8 gates *c* and feeders *d* to 2 parallel conveyors *e*, to screens *f*, primary cone crushers *g*, scalping screens below *g*, short-head cones *h*, gathering conveyors *i*, transfer conveyors *j*, and main conveyor *k* to the mill bins (Fig. 28). For details of this apparatus see items 6 to 11, Fig. 24. Features particularly pointed out by the designer are: (1) the multiple draw gates *c* and feeders *d*, 4 to each conveyor *e* and crusher *g*, operated by push button from the crusher house; each feeder has sufficient capacity for the crusher; two feeders are normally operated at a time at reduced rates; in case of feed failure due to bridging, starting the other two will normally restore flow; one common cause of delay in fine-crushing plants with storage preceding is thus eliminated. (2) Ample non-blind screen capacity, thus eliminating crusher choking due to fines in the feed; this is particularly necessary with cone crushers, if the ore contains clayey fines and moisture content runs above 4 or 5%. The rod-deck screen was found on test to be less subject to blinding than a meshed-screen surface, and placing the rods across the flow reduced tramp oversize in the undersize. (3) Provision of undersize chutes permitting as nearly as possible vertical fall. (4) Elimination of wood and tramp iron by hand picking and ample magnets on belts *e*. (5) Pyramid arrangement of machines with vertical access to all by the crane hooks. (6) Adequate dust control (see Fig. 29). (7) A central lubricating system, which circulates the oil at constant temperature, and sufficient oil-storage facilities, with an oil centrifuge for cleaning the circulating supply when necessary.

Concentrator (Fig. 28) has the typical shape and general machine arrangement of most large modern plants, with the mill bins forming the back, the grinding floor in front of these with a mill-repair and standby bay at one end, rougher and cleaner flotation successively on lower floors below, and regrind on the lowest floor. The slope available was more than was needed, as evidenced by the fact that the working floor for the flotation cleaners is built up some 10 ft. and the drop therefrom to the regrind floor is much greater than necessary. The only uphill counterflow of pulp is that of reground middling.

The only unusual points of design are the high percentage of repair and standby stands for the primary ball mills (4 stands against 16 active mills), which undoubtedly involved provision for future expansion; and the location of the electrical-control room at a point where the responses are not visible to the man at the controls. This is not, however, serious in this case, since the large crane is available to kick mills through fractional turns, when this practice is necessary.

Dust collection systems are installed at the primary crusher, primary-ore bin, secondary-crushing house, and fine-ore bins. Fig. 29, showing the installation in the primary-crusher house, is typical. All dust-making locations, which is to say, all places where dry ore moves rapidly through air, or is stopped suddenly, are enclosed as thoroughly as possible. Thus in Fig. 26 a brattice of rubber belting at *A*, together with the roofed and walled enclosure to the right, substantially encloses pocket *b* at this point, and with the floor above the gyratory, confines the dust formed and suspended in *b*, *e*, *h*, and the gyratory itself. This dust is withdrawn by suction through pipes *a* and *b*, Fig. 29. The ore stream on feeders *j* (Fig. 26) is completely boxed in, as are the chutes *k* and the skirting on conveyors *l* up to the point that the load has settled; these places are served by suction ducts *c*, Fig. 29. The screens, chutes, cones, and the conveyor head boxes and loading points in the secondary-crushing plant are similarly boxed in and connected with another suction system, as are also the bin tops and unloading tunnels.

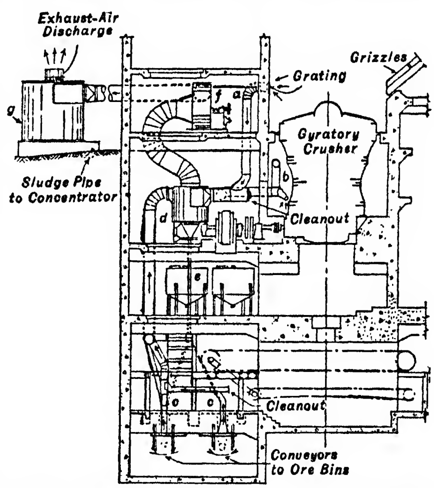

FIG. 29. Dust-collecting system in primary-crusher house at MORENCI.

The layout of the collecting systems at all of the points enumerated above is the same, differing only in size of units. It comprises a cyclone *d* (Fig. 29), which drops out sand for direct return dry to the ore stream, as by pipe *e* leading to the conveyor belts; a centrifugal exhaust fan *f*, with back-curved blades, discharging to a spray collector *g*, comprising a tank with sprayed baffles against which the dust-laden stream impinges, the dust particles being wetted and entering the water film. For detailed discussion of the collecting apparatus see Art. 9. Sludge from all spray collectors flows to the regrind circuit in the concentrator. Estimated air volumes and power consumption for the system are given in Table 27.

Table 27. Dust-collecting systems at Morenci

Location	Exhaust air, c.f. per min.	Static pressure of fan, in. of water	Hp.
Primary-crushing house	40,000	4	20
Primary ore-bin superstructure	20,000	3	15
Primary ore-bin substructure	8,000	4 1/2	10
Secondary-crushing house	40,000	4	20
Conveyor-drive house	3,000	2	2
Fine-ore bins	22,400	3	20
Totals	133,400	..	87

Summary. Three-stage open-circuit crushing in gyratory and cones to $^{3}/_{4}$-in., with scalping screens ahead of each crusher; one-stage grinding to 65 *mog;* all-flotation with 2-stage roughing, pyrite depression from primary-rougher concentrate, middling regrind followed by separate cleaning, with counterflow of regrind-cleaner tailing to the primary rougher.

Aldermac Copper Corp., Ltd. Fig. 30 (*Q* by A. C. King, Mill Sup't).

Location: Aldermac, Quebec, Canada.

Ore: Approximate mineral composition: chalcopyrite, 5.5%; sphalerite, 0.4%; pyrite, 40%; pyrrhotite, 28.1%; insoluble, 26%.

Capacity: 1,000 tons per 24 hr.

Assays: See Table 28.

Table 28. Assays at Aldermac

Material	Per cent.					Oz. per ton	
	Cu	Zn	Fe	S	Insol.	Au	Ag
Feed..........	1.9	0.2	35	32	26	0.01	0.36

24. 1 @ 2-in. Dorrco diaphragm pump; 2 @ 3-ft. cone classifiers in series making overflow at 10% solids and 98% <200-m. to pyrite stock pile, and spigot at 50% solids and 50% <200-m. to 1 @ 8×12-ft. Dorrco filter, cake 7.2% moisture.

Fig. 30. Aldermac Copper Corp.

center of hydraulic gradient. 2 @ 75-hp. motors. 12-in. wood-stave pipe, steel-wire bound. Efficiency, 78%. CONSUMPTION, 3.1 tons per ton of ore; none re-used.

Percentage possible running time: 95; power interruption and repairs are principal causes of lost time.

Building: Timber with shiplap siding covered with white asbestos siding; sloping site; ball-mill floors cement; flotation floors wood grated; floor slope in wet parts, 5/8 in. per ft. Steam heat.

Machinery handling: Hand-operated cranes in crushing and grinding sections; chain blocks in concentration section.

Power: Purchased. Transmitted 92 mi. at 110,000 volts. Motors, 550-volt, 25-cycle.

Transportation: Mill at mine; railroad, 1 1/4 mi. distant; copper concentrate trucked to siding and shipped 1,000 mi. to smelter.

Summary. Run-of-mine to <1/4-in. ball-mill feed by jaw crusher and 2-stage cone series; ball-mill grinding to 48 *mog* in one stage for flotation with cone classifiers guarding the mechanical-classifier overflow; all-flotation concentration, making a bulk copper-iron concentrate by a rougher-scavenger flow, and depressing pyrite therefrom with lime and cyanide.

Britannia Mining & Smelting Co. Fig. 31 (*Q* by A. C. Munro, Sup't of Mills, and his metallurgical staff).

Location: Britannia Beach, B. C.

Ore: Chalcopyrite, pyrite, blende, and minor amounts of chalcocite and bornite in chlorite schist. The primary slime, mostly from the highly oxidized ore from the upper levels, amounts to about 13% of mill feed. The water decanted therefrom carries soluble salts in the following amounts: $CuSO_4$, 0.17 lb. per ton of mine ore; $FeSO_4$, 0.33 lb.; free acid, 0.09%; $CaSO_4$, 1.71 lb.; $MgSO_4$, 0.14 lb.

Capacity: 6,000 tons per 24 hr.

Assays: Feed, 0.80% Cu; copper concentrate, 24 to 27% Cu, 5 to 8% Zn, 31% Fe, 2% insol., 0.15 to 0.21 oz. Au; pyrite concentrate, 0.25% Cu, 50% S, 3% insol.; tailing, 0.1% Cu, 0.001 oz. Au.

Recovery: 89 to 92% Cu.

Ratio of concentration: 25 or 30 : 1.

Water: Piped 5 mi.; consumption, 3 to 4 tons per ton milled; none reclaimed.

Power: Hydroelectric, local and purchased; latter comes 30 mi. at 34,000 volts; 440-volt 60-cycle motors; CONSUMPTION, 22.3 hp-hr. per ton milled.

Labor: Canadian; 105 tons per man-shift operating; 600 tons per man-shift on maintenance.

Running time: 98 to 99%; principal cause of loss, power failure.

Mill building: Sloping site. Steel and concrete, concrete floors slope 1/2 in. per ft. in wet portion. Mill building heated. 30-ton crane in coarse-crushing section; chain blocks and crawls in concentration sections.

Distances: Mine to mill, 3 mi., 20-ton bottom-dump cars; concentrate (10.5% water) shipped 200 mi. by water.

Tailing disposal: Discharged into Sound at tide level.

Cost (1931): 20¢ per ton, of which crushing was 5¢, grinding 5¢, and flotation 3¢. (*IC 6619.*)

Legend for Fig. 31:

1. Coarse crushing is done underground.

2. Grizzly, 6-in. aperture.

3. 1 @ 36×48-in. Blake crusher, 6-in. open setting. 1 @ 24×36-in. Blake stand-by.

4. Feed requires washing to reduce screening difficulties. 3 @ 500-ton coarse-ore bins: 2 @ 500-ton wet-ore bins; feeders with vigorous sprays; 30-in. belt conveyor with sprays.

5. 2 @ 5/8-in. stationary grizzlies, with vigorous sprays.

6. 3 @ 5 1/2-ft. cone crushers, set 5/8-in.

7. Washing elevator.

8. 4 @ 15-ft. washing screens, 3/16×1/2-in aperture.

9. 3 @ 42-in. belt conveyors in series.

44. 1 @ 6-ft. 6-disk American filter.

45. Pump.

46. 1 @ 40×14-ft. and 1 @ 16×14-ft. thickeners.

47. 1 @ 6×10-ft. ball mill.

48. 1 @ 4(wide)×3×30-ft. Forrester machine; air, 1.7 lb. per sq. in., 45 c.f.m. per lin. ft.

Summary. Three-stage crushing from run-of-mine to <1/8-in. with washing and separation of <1/4-in. material with primary slime before secondary crushing. Two-stage grinding to 48 *mog*. Separate sand and primary-slime roughing to make bulk concentrate, which is reground and refloated to depress pyrite. Sand tailing of primary run, after straking and desliming, is reground and recirculated to the sand rougher. Refloated copper concentrate is cleaned once, as is pyrite concentrate refloated at the end of the primary-cleaning run. Regrinding is thus kept down to 12 to 15% of original feed.

Howe Sound, Holden mill, Fig. 32 (H. A. Pearse, Mill Sup't, and V. A. Zanadvoroff, Met., *140 #11 J 31*).

Location: Holden, Wash.

Ore: Chalcopyrite with small amounts of native copper, chalcocite, covellite, and malachite; gold and silver; pyrite and pyrrhotite in the approximate ratio 3 : 1; minor sphalerite and insignificant galena and molybdenite; total sulphides about 20%; in a metamorphosed quartzite cut by diorite and granite dikes. The gold appears to be associated with all the sulphides, but chalcopyrite is the main carrier and pyrrhotite and sphalerite carry least; it is 90% free at 60% <200-m.

Capacity: 2,000 tons per 24 hr.

Assays: Concentrate, 23 to 24% Cu.

Recovery: Cu, 94%; Au, 81 to 83%. About 5% of total gold is heavily coated; some is finely locked in the gangue and some in the pyrite and sphalerite, both of which are depressed to help concentrate grade.

Power: All motors over 50-hp. are 2,300-volt synchronous, thus maintaining an average power factor of 96%. Starting, control, and meter equipment are housed in a separate dustproof building. Units operated by remote push-button control. Crushing-plant conveyors and feeders are electrically interlocked with the crushers and with each other. CONSUMPTION, kw-hr. per ton: Crushing, 2.4; fine grinding, 10.1; flotation, 2.5; filtering, thickening, pumping, 0.7; tailing disposal and return water, 0.6; lighting and miscellaneous, 0.4; total, 16.7.

Labor: 40 operators and helpers on 3 shifts; 8 to 10 mechanics on maintenance on day shift.

Mill building: Steep sloping site. Building steel and concrete; roof insulated with rock-wool on Carey stone and under corrugated iron; walls 3-in. Thermax, corrugated-iron outside, Gunited inside. Heating by unit oil burners at strategic points in lower part of building. Crushing plant is separately housed, and provided with a dust-collecting and air-washing system.

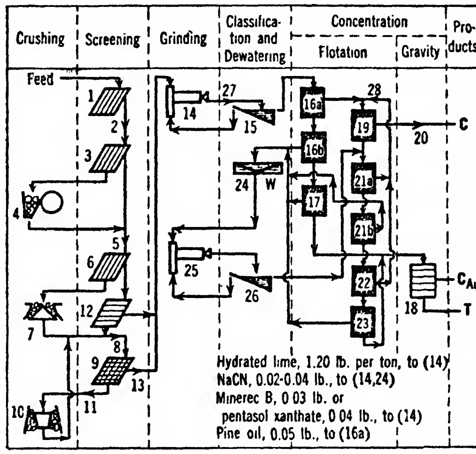
Machinery handling: All main operating floors served by overhead cranes delivering to an inclined hoistway to the shops.

Tailing disposal: Impounded in a 10-acre area close to the mill.

Distances: Mill at mine. Concentrate loaded by conveyor from filter or drier into 5-ton steel containers. These are trucked 12 mi., thence 40 mi. by barge and 4 mi. by truck to the Great Northern

Railroad at Chelan Falls, Wash., whence the concentrate goes by covered cars to the Tacoma smelter. Cranes for handling the containers are provided at all transhipment points.

Costs (cents per ton): Crushing, 9.8; grinding, 19.7; flotation and pumping, 8.6; concentrate handling at mill, 2.0; tailing disposal, 2.5; general, 9.2; total, 51.8.



Legend for Fig. 32:

1. Underground grizzly, 27-in. spacing.

2. 7-ton Granby-type side-dump cars from main haulage tunnel; 1 @ 700-ton mine-ore bin with 1 @ 5×26-ft. pan feeder.

3. Grizzly, 6-in. spacing.

4. 1 @ 36×48-in. Traylor jaw crusher, 5-in. open setting.

5. 1 @ 36-in. belt conveyor with magnetic head pulley and suspended magnet.

6. Grizzly, 1 1/2-in. spacing.

7. 1 @ 4 1/2-ft. standard cone crusher, set 1 1/4-in.

8. 3 @ 24-in. inclined belt conveyors in series; surge bin.

9. 2 @ 4×8-ft. Tyler vibrating screens, 3/8-in. cloth.

10. 1 @ 5 1/2-ft. short-head cone, set 3/8-in.

11. 1 @ 700-ton surge bin; 2 feeders; 1 @ 24-in. conveyor belt with suspended magnet.

12. 1 @ 3×6-ft. Symons rod-deck screen, 3/16-in. openings, run wet to take wet sticky undersize out of the fine-crushing circuit.

13. 1 @ 24-in. belt conveyor, 1 @ 1,500-ton fine-ore bin with 4 feeders; 2 @ 24-in. parallel feed conveyors with weightometers; 1 @ 24-in. distributing conveyor, chutes, and splitters.

14. 4 @ 8×9-ft. Traylor ball mills, direct-connected, 250-hp. low-speed synchronous motors; ball charges about 25 tons each of 2 1/2-in. cast balls. Circulating loads are 400 to 500%, making about 2,000 tons per 24 hr. total feed to mill. Total ball CONSUMPTION, 3.4 lb. per ton; cast chrome-molybdenum liners, 0.25 lb. per ton.

15. 4 @ 7×25-ft. heavy-duty rake classifiers. Overflow 26 to 27% solids; all <65-m., 60% <200-m.

16. 1 @ 5×60-ft. matless-type air cell, 10 ft. deep.

17. As (16). These two cells give a combined primary treatment time of 40 min.

18. 40×40-ft. blanket plant.

19. 1 @ 5×20-ft. deep-type matless cell.

20. 1 @ 30(diam.)×8-ft. thickener, overflow clear; 2 @ 6-ft. 4-disk Eimco filters making cake at 10 to 11% moisture; 1 @ 16-in. conveyor; 1 Lowden concentrate drier to 7 or 8% moisture; used in winter only, to prevent freezing in transit.

21. 1 @ 5×40-ft. deep-type matless cell.

22. 1 Fagergren cell.

23. 4 Fagergren cells in series.

24. 1 @ 50(diam.)×10-ft. thickener, clear overflow.

25. 1 @ 5×8-ft. ball mill.

26. 1 @ 6×23 1/3-ft. rake classifier; overflow 98% <200-m.

27. pH = 9.0–9.5.

28. Generous quantities of water added here to drop fine silica and mica.

FIG. 32. HOWE SOUND, Holden mill.

Summary. Three-stage crushing to 1/4-in.; crusher feeds scalped; last stage a short-head cone in closed circuit; two-shift operation. One-stage primary grind to <65-m.; one-stage regrind of primary and refloated low-grade middling. Concentration by flotation with protracted treatment of primary stream and of primary cleaner tailing, making final tailing over blankets on both streams. Separate regrind of low-grade froth middling and return to the primary-cleaner stream. Froth counterflow on the cleaner stream but not on the primary stream.

The purpose of the separate circuit for middling regrind, and reintroduction to the first scavenger on the cleaner stream rather than to the cleaner is, first, to give opportunity for a second try at depression of Fe and Zn, and second, to force such material to float at least twice on return to the flotation cells, if it is to get into finished concentrate.

Mt. Lyell Mining & Railway Co., Ltd. Fig. 33 (*Q* by C. H. P. Moline and staff; *33 CEMR 75*).

Location: Mt. Lyell, Tasmania.

Ores: A chlorite-quartzite schist carrying pyrite, chalcopyrite and covellite; also a quartzite carrying bornite, chalcopyrite, and chalcocite.

Capacity: 3,200 tons per 24 hr.

Assays: See Table 29.

Table 29. Assays at Mt. Lyell

Material	Percentages				Oz. per ton	
	Cu	Fe	S	Insol.	Au	Ag
Feed	1.45	10	7.2	....	0.013	0.09
Copper conc	25.4	30.8	33.9	....	0.15	1.20
Pyrite conc	0.6	42.7	48.2	5.0	....	....
Tailing	0.17	5.8	2.6	....	....	....

Recovery: 89.5% Cu.

Ratio of concentration: 20.7 : 1, based on Cu concentrate.

Labor: Australian. Tons per man-shift: operating, 50; repairs, 137.

Running time: 97.5%. Motor repairs principal cause of delay.

Water: 2 mi. by gravity from dam in stream. No reclamation. CONSUMPTION, 2.5 tons per ton milled.

Building: Steel frame, galvanized-iron cover; floors concrete at ground level, timber above, slope in wet parts 0.3 in. per ft. Unheated. Site level.

Machinery handling: Air and electric hoists.

Power: Hydroelectric; comes 7 mi. at 6,600 volts. Motors, 500- and 3,300-volt, 50-cycle. 27.4 hp-hr. per ton milled.

Transportation: Railroad at plant. Ore from underground mine comes 1 1/2 mi. by electric haulage through adit; open-cut ore hauled 1 mi. in 12-ton motor trucks to main ore-pass from surface to adit. Concentrate pumped 1,100 ft. from mill to smelter filter plant.

Tailing: Thickened tailing used for mine filling as required; balance, unthickened, to river.

Costs (10/1/39–12/29/40): Crushing, $0.066 per ton; grinding, 0.16; flotation, 0.091; concentrate dewatering, 0.01; conveying and elevating, 0.023; overhead, superintendence, and miscellaneous, 0.117; total, $0.48.

Summary. Crushing from <30-in. to <3/4-in. in 3 stages (gyratory, cone, rolls) open-circuit. Grinding to flotation feed (73% <200-m.) in two stages in ball mills, each stage in closed circuit with individual rake classifiers, all rake-classifier overflows in closed circuit with bowl classifiers feeding sand to the secondary ball mills. All-flotation concentration, making first a differential copper concentrate with Aerofloat, using cyanide as a pyrite depressant, and thereafter desliming and floating pyritic sand with xanthate. Flow of flotation pulp in the copper section is by a 3-stage rougher-scavenger routing; first-stage concentrate is given two cleanings with the usual one-step counterflow of cleaner middlings. Flow in the pyrite section is one-stage rougher-scavenger routing with two-step cleaning of concentrate and both cleaner middlings returned to the rougher cell.

This plant demonstrates the penalty paid for a level-site mill with a complicated flow-sheet in that the installed hp. for pumping is 3 hp-hr. per ton of original feed.

Outokumpu Oy. Fig. 34 (*Q* by E. Mäkinen; *19 MMt 85*).

Location: Outokumpu, Finland.

Ore, approximate composition: Chalcopyrite, 12%; pyrite, 30%; pyrrhotite, 15%; sphalerite, 1%, quartz, 40%, Au, 0.8 gm. per ton, Ag, 12 gm. per ton.

Capacity: 1,000 tons per 24 hr.

Assays: Feed: 4% Cu, 24% S, 42% insol.; Cu concentrate, 22% Cu; sulphur (pyrite-pyrrhotite) concentrate, 44% S; tailing, 0.35% Cu, 8% S with cell 12 (see flowsheet) not yet installed.

Recovery: 92% of Cu.

Ratio of concentration: 5.9 : 1, based on original feed and Cu concentrate.

Labor: Finnish. Tons per man-shift: operating, 20; repairs, 30.

Running time: 97%. Principal loss due to holidays and power interruptions.

Water: Pumped 2 mi. from a small lake. None re-used. CONSUMPTION 4 tons per ton of ore milled.

Building: Concrete. Floor slope in wet part, 2 in. per ft. Heated. Sloping site.

Machinery handling: Power crane.

Power: Hydroelectric (steam reserve); transmitted 200 mi. at 50,000 volts. Motors, 380-volt, 60-cycle CONSUMPTION, 29.8 hp-hr. per ton milled.

Transport: Railroad at property. Mill at mine. Mill to Cu smelter, 150 mi. Pyritic concentrate sold to paper-pulp mills; hauls 100 to 300 mi.

Tailing: Sand to mine fill; slime to lake.

Fig. 34. Outokumpu Oy.

Summary. Crushing from run-of-mine to <3/4-in. ball-mill feed in three stages comprising two jaw crushers and a cone in continuous open circuit. Grinding to 48 *mog* (54% <200-m.) by two-stage ball milling, the first stage open-circuit, the second in closed-circuit with an aerator classifier. All-flotation concentration with rougher-scavenger routing and two-stage cleaning in copper flotation, with regrind of all middling before counterflow to the rougher; two-stage roughing-out of pyritic concentrate with intermediate discard of slime tailing.

In so far as the bulk of the floatable mineral is concerned, this ore is similar to Noranda, but the precious-metal values are much lower. Yet despite the smaller number of cells and shorter length of primary-pulp run at Outokumpu, the total treatment time is substantially the same as at Noranda.

Granby Consolidated M. S. & P. Co. Fig. 35 (*Tref 7/40; 129 J 176*).

Location: Allenby, B. C.
Ore: Bornite, chalcopyrite, chalcocite, and covellite, in an altered silicate gangue. Very hard and tough.
Capacity: 4,500 tons per 24 hr.
Assays and recoveries: See Table 32.

Table 32. Assays at Granby Consolidated

Material	Assays

FIG. 35. GRANBY CONSOLIDATED M. S. & P. Co.

Summary. Six-stage crushing to 4% >8-m.; 2-stage closed-circuit grinding to 3% >65-m. flotation feed and 1-stage regrind of rough concentrate; all-flotation concentration with 1-stage roughing and 2-stage scavenging on the primary flow; regrind of rough concentrate before 2-step cleaning, making slime tailing on the primary-cleaner stream with regrind of primary cleaner sands before counterflow to the rougher.

Crushing costs run almost double the average in copper plants, while grinding costs are about 25% less than average, but this saving is effected by sending a relatively coarse feed to primary flotation and making a relatively high tailing in probable consequence. Total cost is about average.

Mount Morgan, Ltd., Sulphide plant. Fig. 36 (B. W. Lennon, Mill Sup't, *115 Aa 313*).
Location: Mount Morgan, Queensland.
Ore: Chalcopyrite in a pyrite-quartz gangue, with 0.15 to 0.23 oz. Au. Pyrite 25 to 50%. The ore comprises an acidic slime portion, high in cyanicides, the gold and copper contents of which range from 1 1/2 to 2 times those of the granular portion.
Capacity: 1,500 tons per 24 hr.
Assays: See Table 33.
Recovery: See Table 33.
Ratio of concentration: 30 : 1.
[General data continued on p. 65.]

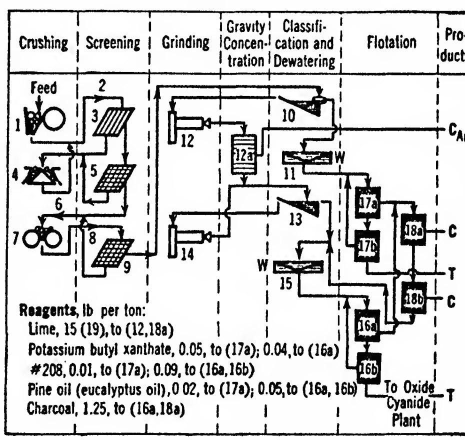
a Primary. *b* Secondary.

Sizing-assay tests (115 *Aa* 357) showed maximum gold losses in the finest elutriated product (<10 or 20-μ) and next greatest in the >100-m. Super-panner tests, supplemented by microscopic examination, showed gold ranging in size from 5×6-μ to 17×30-μ, part clean, part coated with iron oxide, and part locked in quartz and in pyrite in both the slime- and sand-plant tailings.



Legend for Fig. 36:

1. 3 jaw crushers, at 450-, 574- and 650-ft. levels, 5-in. open settings.

2. Underground ore pockets; 5-ton skips; 3,000-ton wooden bin at collar; 6 reciprocating adjustable-stroke feeders; 3 @ 30-in. conveyors in series; magnetic head pulley and suspended magnet.

3. 1 @ 5-bar finger grizzly, 5-in. clear spacing, 25 r.p.m.

4. 1 @ 5 1/2-ft. cone crusher, 200-hp. motor, 120 t.p.h.

5. 2 @ 4×8-ft. vibrating screens, 28° slope, 600 s.p.m., 1×6-in. aperture, 1/2-in. welded-rod screen.

6. 3 @ 26-in. conveyors in series from shaft-house crusher to mill storage; 2,000-ton fine-ore bin (alternatively from the conveyor preceding the bin to a stockpile conveyor, to a stockpile 180×75 ft.×40 ft. high, thence by a tunnel conveyor to the bin-feed conveyor); 3 shaking feeders, 1 push-type feeder.

7. 4 @ 36×18-in. slow-speed (18 to 19 r.p.m.) gear-driven rolls, one flanged and driven, the follower plain.

8. 4 bucket elevators, 18-in. belt, 16-in. buckets spaced 15 in.

9. 7 @ 4×8-ft. Leahy screens, 3/16-in. square or 3/16×3/4-in. rectangular welded-wire cloth.

11. 3 @ 40-ft. and 1 @ 24-ft. thickeners; spigot 22% solids.

12. 2 @ 5 1/2×11-ft. ball mills (as 14).

12*a*. Strakes.

13. 6 @ 8×28-ft. rake classifiers; overflow, 30 to 32% solids; 55 to 60% <200-m.; slope, 2 1/2 to 3 1/4 in. per ft.

14. 6 @ 5 1/2×11-ft. grate-type ball mills (only 4 in use at normal 1,500-ton per day capacity); 80% solids; manganese-steel El Oro type liners, LIFE, 6 mo. end, 12 mo. shell; 14 tons 2 1/2-in. cast alloy balls, 5-lb. per ton; 26 r.p.m.; 150-hp. motors.

15. 1 @ 40-ft. and 2 @ 24-ft. thickeners.

16. 2 @ 14-cell Mt. Morgan-type M-S subaeration machines and one bank of 12 @ 44-in. Fagergren cells (660 r.p.m.), comprising 3 sections; (*a*) 1 to 4 cells of each bank making rough concentrate. Feed about 1,250 tons per 24 hr. See Table 33 for performances.

17. 28 M-S subaeration machines in series. See Table 33 for performances. (*a*) 1 to 4 cells.

18. 4 M-S subaeration machines; (*a*) cell 1 ± cell 2; (*b*) cells 3 and 4 ± cell 2. Cell 2 is switched, according to smelter requirements and assays of the concentrates, from (*a*) and (*b*).

19. Separate treatment of slime has reduced lime consumption from 45 lb. per ton of crude.

Fig. 36. Mt. Morgan, sulphide plant.

Power consumed: 29.3 hp-hr. per ton.
Running time: 94.4%; excluding holidays and causes outside of the mill, the figure is 99.6%.
Costs: (Labor at $18 per 40-hr. week.) Coarse crushing, $0.06; fine crushing, 0.10; grinding, 0.30; flotation, 0.33; concentrate handling, 0.06; tailing disposal, 0.06; superintendence and overhead 0.26; total, $1.17 per ton. (1939, $0.99 per ton, *32 CEMR 108.*)

Summary. Three-stage crushing from run-of-mine to <$^3/_{16}$-in.; 2-stage grinding in ball mills, the first in open circuit, with a strake between stages. All-flotation concentration with separate rougher treatment of primary slime, both rougher circuits having simple rougher-scavenger routings, with one cleaning of combined primary concentrates in 2 stages to permit 2 grades of final concentrate; cleaner tailing returned to the clean-ore rougher circuit via dewatering.

Noranda Mines, Ltd. Fig. 37 (*Q* by C. G. McLachlan, Concentrator Sup't, and W. B. Boggs, Smelter Sup't; *112 A 570*).

Location: Noranda, Que., Canada.
Ore: Chalcopyrite, 4 to 8%; pyrite, 20 to 30%; pyrrhotite, 50 to 60%; Au, 0.12 to 0.20 oz. per ton, Ag, 0.20 to 0.30 oz. per ton; insol., 15 to 20%.
Capacity: 3,000 to 3,200 tons per 24 hr.
Assays: Feed, see *Ore* above; concentrate, see Table 34, item 61; tailing, see Table 34, items 44 and 45, 62, and 41.

Recovery: Cu, 96 to 96.5%; Au, 85 to 90%.
Ratio of concentration: 6 to 8 : 1.
Labor: Canadian. Tons per man-shift: operating. 48; repairs, 375; including cyanidation but not coarse and intermediate crushing.
Running time: 97.6%. Principal causes of loss: ball-mill repairs, 1.1%; electrical, 0.5%; general mill shutdowns, 0.5%.
Water pumped 2 mi. through wood-stave pipe from a lake at a consumption of 145 hp. CONSUMPTION is 2 to 2.4 tons per ton of ore with less than 2% re-used.
Building: Steel frame with brick walls; concrete floors, slope in wet part, $^1/_4$ in. per ft., which is insufficient; heated; level site.
Machinery handling: Power cranes throughout.
Power, purchased, transmitted 55 mi. at 110,000 volts; motors, 550-volt, 25-cycle; 33.6 hp-hr. per ton of ore milled.
Transport: Railroad at plant; ore comes by belt conveyor from mine shaft to mill; concentrate, 550 ft. by conveyor to smelter.
Tailing is pumped $^3/_4$ mi. through 9-in. wood-stave pipe to usual type of tailing dam.

Summary. Crushing from 36-in. run-of-mine to <$^3/_{16}$-in. ball-mill feed size in four stages comprising a jaw crusher, standard cone and short-head cone in series, open-circuit, followed by rolls in closed circuit. Grinding to 48 *mog* (48% <200-m.) primary flotation feed in two ball-mill stages, the first open-, the second closed-circuit, with three subsequent stages of tailing regrind, and one stage of middling regrind, each followed by further flotation stages. Substantially all-flotation concentration, with provision for sending the main pulp stream over blanket strakes at a point about halfway through the primary run and at the end thereof, if desired. Pyritic sand tailing from one of the side streams goes to cyanidation (see below). There are nine flotation stages on the primary pulp stream, divided by two regrind steps into three groups of three stages each. Finished concentrate is taken from the first cell in each group, the remaining two cells of the group furnish one side stream for cleaning and one scavenger for recycle through a grinding circuit to the head of

its respective group. Primary cleaning makes finished concentrate in groups 1 and 3. Primary-cleaner tailings return to the main pulp stream in the group from which they were drawn, being reground in groups 1 and 3 but not in 2. In group 2 primary-cleaner side-stream is recleaned twice; secondary-cleaner tailing returns to the primary cleaner circuit the tertiary-cleaner circuit follows a rougher-scavenger routing with open-circuit regrind and recycle of the sand tailing within the circuit. The sand portion of the tailing discharge from this circuit goes to cyanidation.

Maintenance of a reasonably oxidizing condition in the pulp, which is essential to speed and completeness of flotation, is one of the principal difficulties with this massive-sulphide highly pyrrhotitic ore. Hence an aerating step precedes each section of the flotation on the primary pulp stream and, as well, the middling re-run on pyrite cleaning.

Tennessee Copper Co. Fig. 38 (*Q; 138 #10 J 40; 153 A 345*).

Location: Copperhill, Tenn.

Ore: Massive sulphide; chalcopyrite, pyrrhotite, pyrite, marmatite, sphalerite, and small amounts of silicates and carbonates

Capacity: 1,200 tons per 24 hr.

Assays: Feed: Cu, 1.5%; Fe, 27%; Zn, 1.0%; S, 19%; copper concentrate: Cu, 20%; iron concentrate, 53.5% Fe; zinc concentrate, 49% Zn.

Recoveries: Cu, 92%; Fe, 71%; Zn, 45%.

Ratios of concentration: Cu, 16.0 : 1; Fe, 2.7 : 1; Zn, 100 : 1.

Power: Purchased; comes 25 mi. at 66,000 volts; motors, 2,300- and 220-volt, 60-cycle. CONSUMPTION: 22 hp-hr. per ton milled.

Water from neighboring streams; pumped 1.5 mi. with power consumption amounting to 2 hp-hr. per ton of ore; CONSUMPTION, 3 1/2 tons per ton of ore, none re-used.

Labor: American; tons per man-shift: operating, 103; repairs, 86.8; total, 47.5.

Running time: 93.2%.

Mill building: Slightly sloping site; steel frame covered with sheet iron; operating floors wood, slope 1/2 in. per ft. in wet part. Heated. Power crane in coarse crushing; chain blocks in fine crushing; power crane and chain blocks in concentrator.

Transportation: 1 1/2 mi. mine to mill by standard-gage railroad; 4 mi. from mill to copper smelter and acid plant; zinc concentrate shipped away.

Tailing disposal by gravity flow to a tailing dam.

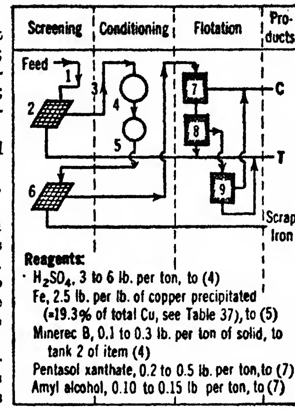
FIG. 38. TENNESSEE COPPER CO.

Summary. Two-stage crushing; 1-stage open-circuit rod milling and 1-stage closed-circuit ball milling to flotation-feed size; all-flotation concentration making a bulk copper-iron concentrate and a rough zinc concentrate on the primary run; bulk concentrate cleaned, reground, and refloated to depress zinc and iron; copper float refloated in 3 steps, making finished copper concentrate in the first, middling for recleaning in the second, and middling for recirculation to the primary grinding circuit in the third. Depressed zinc-iron reactivated with copper sulphate, iron further depressed by lime, and a finished iron concentrate made by floating away a rough zinc concentrate which is recleaned twice.

Ohio Copper Co. Fig. 39 (*Tref 6/41*).

Location: Lark, Utah.
Ore: Tailing from gravity concentration; sulphide and soluble copper minerals.
Capacity: 1,000 t.p.d.
Assays: See Table 37.
Recovery: See Table 37.
Ratio of concentration: 63 : 1.
Water: From mine; slightly acid and contains soluble salts, but is not corrosive. CONSUMPTION, 2.3 tons per ton of ore; none reclaimed.
Running time: 99%, Sept. 1940.
Tailing flows by gravity to ponds behind dams constructed by dragline during summer and fall.
Costs, cents per ton (Sept. 1940): Sluicing, 5.3; milling: labor and insurance 4.4, power 5.6, reagents 4.0, iron 2.5, other supplies 1.7, total 18.2; mill maintenance, 3.2; tailing disposal, 2.0; operating overhead, 1.9; total, 30.7; equivalent to 4.4¢ per lb. of copper recovered.

Legend for Fig. 39:



1. 2 monitors, 7/8-in. nozzles, 70 to 90 lb. per sq. in.; pit launders, 2 1/2% grade; wooden grid, 1-in. spacing; wooden sump; 6-in. Hydroseal pump, rubber lined; life of rubber-covered impellers and rubber bell liners, 10 mo.; rubber shell liners, 5 mo.; 5 1/2-in. wood pipe 3/4 mi. to mill; surge tank with orifice discharge; sampler.

2. 1 @ 4×7-ft. trommel, 16-m. stainless-steel cloth; trommel frame of Everdur, rubber, and stainless steel.

3. 1 @ 6-in. Hydroseal pump as in (1). Pulp about 30% solids.

4. 3 @ 10×10-ft. rubber-lined wood-stave concrete-bottom Devereaux tanks in series; rubber-covered ship-type impellers (LIFE, 18 mo.). Rubber-covered wood well (LIFE, 4 to 6 mo.). About 5 lb. per ton of ore of 60° Bé H_2SO_4 added to first tank, to maintain 0.5 to 1 lb. of free acidity in solution at the outlet of the third tank. Contact time, 30 min. About 1 lb. Cu per ton of ore is dissolved by the acid.

5. 3 @ 6×6-ft. rubber-lined wood-stave (fir, LIFE 3 yr.) Devereaux tanks, with 32-in.-diam. rubber-covered wood center wells (LIFE, 6 mo.), in series. 30-in. 4-blade cast-iron ship-type impellers driven 250 r.p.m. by 15-hp. motors; life 12 to 15 da. Shredded tin cans (pieces about 4 in. square) not detinned added to agitators in an amount equivalent to about 0.6 ton of iron per ton of solids (ratio of iron to solution maintained about 1 : 4 by weight; better rate of precipitation and lower soluble-copper tailing obtainable at ratio of 1 : 2, but this is not possible mechanically in the existing arrangement). Contact time, 5 min.; 82% precipitation of dissolved Cu; loss dissolved Cu per ton of ore, 0.22 lb. (see Fig. 40); about 50% of dissolved Cu precipitated in first tank, 25% in second, 5% in third. Iron consumption about 2.5 lb. per lb. of Cu precipitated. Punched-copper plate screens between precipitators.

6. 1 @ 36-in. trommel with copper covering, 0.5-in. aperture.

7. Cells 1 of 3 @ 8-cell 41 1/2-in. Denver Sub-A flotation machines in parallel; pH about 4.7; recovery drops if pH rises above 5.3. All cells of wood, rubber-lined; impellers, wearing plates and lower end of shaft rubber-covered. Life of impellers 10 mo. in No. 1 cell of roughers; 18 mo. in No. 8 cell of scavenger; about twice these figures in cleaners. Life of wear plates: 9 mo. in cells 1 of roughers; 24 mo. in cells 8 of scavengers.

8. Cells 2 to 8 of (7).

9. 1 @ 8-cell 41 1/2-in. Denver Sub-A flotation as (7).

FIG. 39. OHIO COPPER CO.

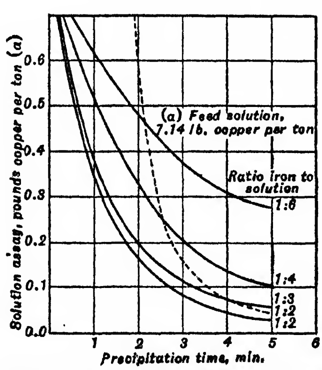


FIG. 40. Time-precipitation curves at OHIO COPPER CO.

Table 37. Metallurgical data, Ohio Copper Co.

Item	Assay, % Cu	% of total Cu
Feed..........	0.48	100.0 *a*
Concentrate...	22.56	74.2
Tailing........	0.13	25.8 *b*

a 13.5% water-soluble; 19.3% water- and acid-soluble; 84.4% of soluble copper precipitates as cement copper.

b About 65% of tailing loss is in rougher tailing; more than half of this is oxidized. Cleaner tailing assays consistently 0.4 to 0.6% Cu irrespective of grade of feed to cleaners; hence scavenger concentrate is kept of as high grade as possible (about 8% Cu) in order to reduce tonnage of cleaner tailing.

Summary. Scalping waste at 16-m.; leaching with dilute acid; precipitating cement copper *in the pulp* with scrap iron; floating sulphides and cement copper together by a rougher-scavenger flow with one-stage cleaning of scavenger concentrate and discard of cleaner tailing.

17. GALLIUM

Uses. Dental alloys; backing of optical mirrors; filling for quartz-tube thermometers for temperatures up to 1,000° C., for which purpose the Ga must be exceptionally free from oxide and impurities, especially Zn and As. Ga-Cd and Ga-Zn alloys have proved useful in manufacture of vacuum and metal-vapor lamps.

Occurrence. A frequent accessory in zinc sulphide and oxidized ores; certain blende concentrates from the Tri-State district are estimated to contain 3 to 5 oz. Ga per ton.

Gallium tends to concentrate in the nonvolatile residue of zinc redistillation retorts, in which the temperature (1,000° C.) is about 350° lower than usually prevails in the primary ore retorts. Unlike germanium (Art. 18), gallium in usual proportions introduces no particular difficulty in electrolysis of zinc from sulphate solution; hence any output of gallium is more likely to come from retort smelters.

Production. Germany has been reported (1938) as producing about 50 kg. of gallium per year, for sale at 10 Rm. per gram.

Treatment. See under *Occurrence.*

18. GERMANIUM

Uses. No outstanding uses yet discovered. Addition of 1.2 to 1.6% Ge to Duralumin and similar alloys is reported to improve strength and rolling properties; a German patent covers Al-Mg-Ge alloy (up to 5% Ge). On substituting GeO_2 for SiO_2, four types of glass were found to have wider dispersion and higher refraction than SiO_2 glass; hardness was the same, but melting point was lower, density greater, and coefficient of thermal expansion higher.

Occurrence. Three minerals (all scarce) contain notable proportions of Ge: argyrodite ($3Ag_2S \cdot GeS_2$) with 5 to 7% Ge, found at Freiberg, Saxony, and Ormo, Bolivia; canfieldite (similar composition) found in Bolivia; germanite, Ge up to 6.2 and 8.7%, found with copper sulphide ores at Tsumeb, W. Africa. Germanium is a frequent accessory in zinc ores, both sulphide and oxidized, particularly in blendes from the Tri-State district, Wisconsin, and Mexico; 550 kg. of a Mexican blende yielded 5 gm. Ge. Smithsonite from the HUDSON mine, Salem, Ky., contained 0.01% Ge, and water from the same mine gave 0.29% Ge in its total solids. Up to 0.25% Ge has been found in the spelter and zinc oxide made from Tri-State and Wisconsin blendes, being highest in those oxides made by burning mixtures containing spelter retort residues (*9 IEC 661*), indicating that Ge is less volatile than Zn. Flue dust from roasters at Freiberg, where argyrodite occurs, contains no germanium. Germanium is particularly obnoxious in $ZnSO_4$ electrolyte; as little as 0.1 mg. per liter interferes and 1 mg. prevents deposition; corrected by addition of Fe to initial charges (if ore will not provide at least 10 gm. Fe per liter) subsequent precipitation of which occludes Ge along with other impurities (*57 AES 279*). Germanium (estimated at 0.1%) was found in enargite from Butte, Mont., and the SANTA FE mine, Chiapas, Mex.; also (about 0.01%) in enargite from Central City, Colo., and the BRADEN mine, Chile (*49 ACS 3031*).

Treatment. Most likely sources of germanium (if need should arise) would be the clinker from primary zinc retorts and the residues from extraction and purification of $ZnSO_4$ electrolyte. Winkler decomposed argyrodite by fusion with Na_2CO_3 + S at red heat (*VII Mellor 274*). Germanium is separable from its usual associates by volatilization of its tetrachloride (atmosphere of chlorine prevents simultaneous evolution of arsenic); also (except from As and Sn) by precipitation with H_2S in *strongly acid* solution; from As, by fractional distillation of $GeCl_4$(b.p., 86°) from $AsCl_3$ (b.p., 129°). The oxide (GeO_2), from calcination of GeS_2, can be reduced to porous metal by carbon at a little above 1,000° C., and remelted under salt or borax (*31 JPC 1429*).

19. GOLD AND SILVER

Gold

Uses. The principal use is for coinage, for which purpose an alloy with copper is used. The composition of the standard coinage alloy in most countries is 900 parts gold and 100 parts copper (900 fine); Great Britain and Portugal, with standards 916.6 fine, are the principal exceptions. Jewelry is commonly manufactured from gold-copper alloys. The fineness of jewelry gold is expressed in carats. Pure gold, 1,000 fine, is 24 carat. With this basic relation any other fineness or carat rating can be computed by simple proportion. Gold-silver alloys are used to some extent in jewelry manufacture, having a paler color than the usual alloys. An alloy of 750 parts gold and 250 parts iron is sometimes used by jewelers to make BLUE GOLD. A small amount of gold as leaf is used for gilding and gold lettering. Ruby-gold glass is a solid solution of colloidal gold in glass. Potassium aurocyanide is used in gold-plating by electrolysis. Certain gold salts are used in photography.

Ores. The economic minerals are native gold and the tellurides calaverite, sylvanite, krennerite, and nagyagite. The principal ores are those containing native gold as grains of varying, but usually minute, sizes, scales, and foil-like coatings; normally alloyed with more or less silver, copper, iron, and metals of the platinum group; associated almost invariably with quartz and, except in oxidized zones near the surface, with sulphide minerals. Of the latter the most common, in order of frequency of association, are pyrite, galena,

chalcopyrite, sphalerite, arsenopyrite, tetrahedrite, and pyrrhotite. Less frequent sulphide associates are bornite, chalcocite, molybdenite, polybasite, proustite, stephanite, stibnite, and tennantite. In oxidized ores the common metallic decomposition products of the original gold associates are the oxides of iron and manganese and the carbonates and silicates of copper. The usual rock-forming gangue minerals accompanying quartz are calcite, sericite, fluorite, rhodochrosite, siderite, feldspars, and clay minerals. Native gold also occurs mechanically mixed with loose, water-sorted material (PLACERS). Usual associate residual-sand minerals are listed on p. 75. The tellurides (sylvanite and calaverite) ordinarily occur associated with pyrite and with one or more of the other sulphides named above.

Production. Gold in greater or less quantities is produced in more than 40 countries. World production for the more significant years from 1913 to 1938 is shown in Table 38.

Selling. Art. 50.

Table 38. World production of gold (thousands of ounces, troy) (*MI*)

d Preliminary estimate.

TREATMENT

The factors that influence the choice of a method of treatment for a gold ore are no different from those that must be considered in deciding on a method for any ore. They comprise the technical and economic limitations and advantages, derived in detail and balanced according to the exigencies of the particular situation. But because of the high unit-weight value of gold, the variety of reasonably efficient recovery methods available, the relatively large variation in simplicity, first cost, operating cost, and results that they will effect, and the tremendous variety in type of ores, determination of the best answer in any particular case may be a man-size technical job and a matter of opinion from an economic standpoint. Gardner and Johnson (*IC 6800*) list as major considerations in choice of a type of mill: (1) nature of the valuable and valueless minerals; (2) amenability of the valuable minerals to the available methods of treatment and the effect of the gangue minerals thereon; (3) quantity of ore developed [and amount justifiably suspected, *Ed.*]; (4) comparative treatment costs by the different methods applicable; (5) comparative marketing costs; (6) comparative installation costs; (7) methods of financing available and their comparative costs.

Gardner and Carpenter (*Meet'g A.I.M.E.; San Francisco, Oct., 1935*) presented and compared the flowsheets of 13 small mills treating oxidized siliceous gold-silver ores from the one region around Virginia City, Nev.; they pointed out that the flowsheets range from simple amalgamation with a recovery of about 60% to straight cyanidation with a recovery of upward of 95%, depending to a considerable extent, probably, on financing factors, but to a considerable extent also—on the evidence—on personal predilections of the designers.

Properties of gold important from the standpoint of milling ore are its extremely high specific gravity (15.5 to 19.3, depending upon the amount of alloying metal admixed); the

fact that mercury wets it readily in the presence of water (AMALGAMATES it; Sec. 14, Art. 5); its more or less ready solubility, under proper conditions, in dilute aqueous solutions of alkaline cyanides to form relatively stable compounds of the form $K \cdot Au(CN_2)$; and its response, particularly as naturally alloyed, to flotation collectors. Gold in telluride form does not amalgamate, and is little acted upon by ordinary cyanide treatment.

Milling characteristics of precious-metal ores. The ores of gold and silver constitute an endless variety, but from the standpoint of mineralogical characteristics important in milling they may be classified as follows:

1. Placer deposits, in which the gold occurs free or substantially so, and is relatively coarse. The usual treatment comprises gravity concentration followed by or coincident with amalgamation.

2. Simple free-milling vein deposits, comprising those in which the gold is relatively coarse and amalgamable, the sulphide content is low and nonarsenical, oxidized compounds of bismuth and antimony are absent, and the gangue is substantially free from talcy, clayey, and graphitic constituents. Treatment is by amalgamation, supplemented usually by gravity concentration with amalgamation of concentrate, and frequently further supplemented by cyanidation of tailing. Recovery by amalgamation alone after crushing to 35-m. may be 50 to 70%, with increase to 75 or 85% by supplementing with gravity concentration. It should be borne in mind that free-milling ores occur usually in shallow oxidized surface zones and that their amalgamable character may change markedly when the unaltered zone is reached.

3. Simple nonamalgamable ores, comprising low-sulphide or nonsulphide ores in which the gold is coarse enough to amalgamate, but is so coated on the surface (RUSTY) that it is not wetted by mercury; and those in which the gold, although bright when freed, is so fine that it will not settle sufficiently in a flowing pulp to come into contact with the mercury. The first class is usually treated by gravity concentration to recover the rusty gold, concentrate is ground, with or without chemicals, to remove the rusty coating, and is then amalgamated. If there is sufficient fine gold to justify the expense, the gravity tailing is cyanided; this is the usual case. The second class of ores is usually ground fine and cyanided. Rusty gold gives trouble in flotation (see Sec. 12, Art. 49).

4. Sulphide ores low in valuable base metals. The sulphides may or may not contain minerals that are refractory to cyanidation, and the gold may be associated with one of the sulphides, substantially with all of the sulphides, with the gangue only, or with both gangue and sulphides. The underlying principles of treatment are that concentration will separate sulphides from rock-forming minerals, that cyanide will dissolve the gold, and that roasting will remove cyanicides. Application of these principles results in all-cyanidation for ores with gold distributed through both sulphide and nonsulphide gangue with no cyanicides present; separation of sulphides from nonsulphide when the values are concentrated in the sulphide (or when they are in the gangue and the sulphide contains cyanicides), with appropriate treatment of the separated parts, which may be smelting of sulphide, cyanidation of sulphide with or without prior roasting, or cyanidation of nonsulphide. Recovery by cyanidation will normally run 90% upward to 98%; flotation recoveries cluster, in general, between 80 and 90%, but may easily run higher.

5. Sulphide ores relatively high in valuable base metals, with an important gold content, or with the gold a minor constituent. Economics usually demand recovery of the base metal or metals (*e.g.*, Pb, Cu, Zn) and, since the gold will normally follow these concentrates to a greater or less extent, and smelting such concentrate gives the highest economic yield of combined values, the concentrate is shipped to smelters. If tailing contains sufficient precious metal, it is cyanided.

In addition to the principal ore characteristics above listed, minor components of the ore often have a determinative effect on the method of treatment. TELLURIDES will not amalgamate directly. ARSENIC, ANTIMONY, and, to a lesser extent, BISMUTH MINERALS sicken mercury by coating the surface with a solid film which prevents gold from making effective contact with the liquid metal, and which promotes flouring (Sec. 14, Arts. 5, 6). The sulphides realgar and orpiment and partially oxidized stibnite, arsenopyrite, and other complex arsenic and antimony minerals are particular offenders. Pyrrhotite and chalcopyrite may also tend to sicken the mercury in barrel amalgamation (*Bul 342 CIMM 407*). These substances also react with and consume cyanide, by rendering it into forms incapable of dissolving gold (FOULING), and, being readily susceptible to oxidation, they deoxidize cyanide solutions and thus remove an essential constituent in the cyanide-gold reaction. OXIDIZED MINERALS of the HEAVY METALS, particularly those of copper and iron, also react with cyanide to form complex ions which render the cyanide substantially inactive. CARBONACEOUS MATERIAL, ranging in antiquity from living matter in the water, through spilled lubricant, to graphite in the ore, tends to consume cyanide, foul solutions, and prematurely precipitate dissolved gold. TALCOSE and CLAYEY MINERALS, particularly in the presence of lubricant introduced in mining, tend to sicken mercury, come up with concentrate in flotation, and cause slow settlement and filtration in cyanidation.

General practice on arsenical ores is to cyanide directly, if the arsenic content is low and in the form of fresh arsenopyrite and there is not too much pyrrhotite present. With higher As content, or with ores that TARNISH (oxidize) quickly or are already noticeably oxidized at mine, general procedure is to float, roast concentrate, and cyanide calcine. This is the practice at LAKE VIEW AND STAR, GREAT BOULDER, BOULDER PERSEVERANCE, and WILUNA in Australia, at GOLDEN CYCLE in the United States, and at a number of the

mills in the Little Long Lac and Sturgeon River regions in Canada. SOUTH KALGURLI and GOLDEN CYCLE (custom) roast the whole ore. Since gold coarser than 40-m. is not recoverable by flotation, some form of gravity concentration must appear in these flowsheets; usual practice is to put this operation in the primary-grinding circuit.

Several refractory ores were tested at the laboratory of the Council for Scientific and Industrial Research in Australia (*32 CEMR 152*). A pyrite-arsenopyrite concentrate (86% >100-m.) containing upward of 2.3 oz. Au per ton yielded nothing to amalgamation as received, but 53% recovery was made after regrinding to 85% <200-m., and cyanidation of amalgamation tailing raised recovery to 92% with a consumption of 6.5 lb. cyanide per ton of concentrate. Roasting, with amalgamation and cyanidation of calcine, without regrinding, yielded 97.6% of the gold with a consumption of 10 lb. cyanide and 9.7 lb. lime per ton of calcine. An As-Sb concentrate assaying 15.3% As, 1.3% Sb, 28% Fe, 28.2% S, the principal minerals being pyrite and arsenopyrite, yielded 33.2% of the gold content by amalgamation as received; on regrinding the mercury sickened. Cyanidation of amalgamation tailing raised extraction to 89% with consumption of 7.3 lb. cyanide and 7.5 lb. lime. Regrinding amalgamation tailing to 200-m. before cyanidation raised total extraction to 94.1% but also raised reagent consumption to 13 lb. cyanide and 25 lb. lime. Roasting, water-washing unground calcine, amalgamating and cyaniding yielded 97% extraction with a consumption of 15.7 lb. cyanide and 6.1 lb. lime per ton of calcine; regrinding calcine to 98.2% <200-m. after washing but before amalgamation and cyanidation raised yield to 98.2%, but cyanide consumption went up to 23.4 lb. An oxidized ore containing 0.1% Bi yielded 26% of the gold by straking at 25-m. and 90% (total) on cyanidation of strake tailing for 20 hr., with a consumption of 0.54 lb. cyanide and 2 lb. lime. Grinding strake tailing to 78% <200-m. before cyaniding gave 95.8% total yield with 0.31 lb. cyanide and 3.9 lb. lime, while at 98.2% <200-m. the corresponding figures were 97.2, 0.72, and 4. Flotation with amyl xanthate and copper sulphate recovered 47 to 68% of the Bi in a concentrate assaying 10 to 14% Bi (20% Bi is minimum salable grade) but the gold content was too high. A concentrate containing As and Cu consumed an excessive amount of cyanide as received. Roasting, straking calcine and amalgamating strake concentrate, water-washing tailing, and then cyaniding gave 43% recovery of gold with a consumption of 11.3 lb. cyanide and 1.9 lb. lime per ton of calcine. Substituting an acid wash for the water wash to remove substantially all Cu produced 90.5% extraction with loss of 3.8 lb. cyanide and 1.9 CaO per ton of calcine. Another Bi-bearing ore in which the gold occurred in stibnite (*32 CEMR 49*) was floated 10 min. at 74% <200-m., *p*H = 6, using 1 lb. per ton lead acetate to activate the stibnite, plus 0.5 lb. amyl xanthate, 0.16 lb. pine oil, and 0.16 lb. cresol. Concentrate assayed 55.6% Sb and 2.77 oz. Au from feed assaying 9.65% Sb and 0.545 oz. Au. Recovery was 83.6% of Sb and 74.2% of Au. Recovery without the acetate was 60% Sb; additional acetate showed no improvement. Greenwood (*103 Aa 220*) states that Australian practice in treatment of refractory ores tends toward trakes in the primary grinding circuit, flotation, roasting of concentrate, straking calcine, and then cyaniding. At LAKE VIEW AND STAR, with such a flowsheet, 18% of the gold is recovered on the grinding strakes and 14% on the calcine strakes; flotation concentrate assays 3.3 oz. Au, and mill tailing is 0.031 oz. from a mill feed of 0.345 oz.

Hargraft (*43 CIMM 576*) has analyzed practice in the Little Long Lac and Sturgeon River areas in Canada where the ores all carry arsenic, ranging from 0.2 to 1.6% from mill to mill, iron ranging from 1 to 17%, sulphur from 0.6 to 9%, and copper from a trace to 0.01%. The tendency for cyanide solutions to foul increases with the As content of the ore. Five of the mills cyanide raw ore; the other five float, roast concentrate, and cyanide calcine. Much of the gold is fairly coarse. All the mills have some form of concentration in the grinding circuit; two use blankets, five have jigs, two use flotation (unit cells) alone, and three use both flotation and gravity concentration, the gold being too coarse to float. Recoveries in these apparatus range from 22 to 89% of the total gold saved. Grinding-circuit concentrate is amalgamated at six mills.

Hand picking. Since cyanidation is a part of most gold flowsheets, and since it normally requires very fine grinding for high extraction, reduction of mill tonnage is an important consideration. Hence picking is practiced wherever it will remove any appreciable tonnage assaying near the content of normal mill tailing. Von Bernewitz (*138 J 135*) noted that picking is practiced at ALASKA JUNEAU, CRIPPLE CREEK, HOWEY, KOLAR, MORRO VELHO, RAND, and YELLOW ASTER, with 5 to 50% of mine ore removed, and stated that the practice is increasing.

Flowsheets for the treatment of gold and silver ores may be classified from the standpoint either of the kind of ore treated or of the method of separation employed. Ultimately, of course, both methods of attack come to the same point, in that the flowsheet is adapted to the ore. For purposes of comparison, however, grouping on the basis of method gives a simpler arrangement and a more logical development, for the reasons, perhaps, that ores are more complex than treatment methods, and less subject to classification, and further that ores vary in composition from working face to working face in a given mine, or from mine to mine in a group, all feeding the same mill, and the mill flowsheet becomes, under such circumstances, a compromise of methods in which the best treatment for a minor constituent is sacrificed to the aim of an economic optimum for the whole.

Separation methods applicable to gold and gold-silver ores are amalgamation (Sec. 14, Arts. 5 to 8); gravity concentration, particularly sluicing, straking, fine jigging, and tabling (Sec. 11); flotation (Sec. 12, Art. 49), cyanidation, and smelting. Silver, when it occurs

other than as a minor associate of gold, is usually so closely associated with copper or lead minerals that it remains locked with them in ordinary grinding, or goes with them, even if freed, when subjected to ordinary methods of concentration, so that separation is deferred to smelting treatment.

The primary desideratum in precious-metal separations is recovery in metallic form at the mill, since this both reduces freight and separation costs (by eliminating shipment to a smelter and smelter charges), and, by making cash returns quickly available, decreases the amount of working capital necessary. Amalgamation and cyanidation both yield bullion at the mill. Hence one or both of these methods is normally practiced, if the ore is amenable. Nonamenability may flow from minuteness of size of the precious-metal particles, or from association with minerals which interfere with the working of the processes. In either case concentration is utilized as a means of reducing bulk to an extent that makes more intense treatment by amalgamation or cyanidation economically possible, or to get the values into the best shape for final separation by smelting. Costs of ultimate separation increase from simple amalgamation to flotation with smelting of concentrate; the following list comprises an arrangement of treatment methods and combinations thereof in general order of increasing total charges against the gold, which embraces most flowsheets.

1. Amalgamation only. Applicable to clean primary ores, and to fully oxidized surface ores of gold in which the gold particles are not too fine to settle in a shallow flowing stream of water, and are not rusty. Plants using amalgamation only are those which serve small mines, usually in the prospecting stage, extracting high-grade ore. Typical examples are reported from northeastern Oregon (*IC 7015*).

At the GLEASON MINE a highly oxidized quartz ore is fed directly into a battery of 5 @ 650-lb. stamps, crushed through a 45-m. screen, and passed over an amalgamating plate sending tailing to waste. A recovery of 90% from $40 ore is reported. The power plant consists of a 12-hp. steam engine and a 14-hp. wood-burning boiler. See also Fig. 78.

2. Gravity concentration + amalgamation. Applicable to ores in which gold is relatively coarse, but either coated, or associated with sulphides not harmful to amalgamation, or ores in which the amount of gold is very small (placers). In any case the initial recovery is made by concentration, and concentrate is amalgamated, either in the concentrator (*e.g.*, mercury in sluice riffles), or in a barrel or the like, with more or less regrinding, if necessary to render the particles amenable to mercury wetting and collection.

This is the typical treatment scheme for placers (Art. 20), for small mills to treat high-grade lode ores in the development stage, and, at a few plants, for the final mill for such ores. For many years it was the only type of mill used for ores such as those on the Mother Lode in California (see *IC 6476*, ARGONAUT MILL). For recent Mother Lode practice see IDAHO-MARYLAND (Fig. 64) and also p. 99.

At MONT TSI, Belgian Congo, ore is ground in a Chilean mill with mercury, passes through an amalgam trap, thence over blanket tables, is thickened, ground in a ball mill-classifier circuit with Hg, passes through an amalgam trap, and thence over blankets which make final tailing. All concentrates are barrel-amalgamated.

3. Amalgamation ± gravity concentration + cyanidation. Applicable to clean ores containing gold of a wide range of sizes, a part too fine for amalgamation and a part too coarse for rapid solution by cyanide.

4. Cyanidation only. Applicable to clean ores with gold finely dispersed, sulphide content relatively low, and at least an appreciable part of the gold in the nonsulphide mineral. See *Rose and Newman; Dorr.*

5. Cyanidation + concentration + cyanidation of concentrate. Used with clean ores containing a relatively small amount of pyrite in which the gold is extremely fine. The ore is usually ground in cyanide solution, a sand-slime separation made, pyrite floated from the sand, concentrate reground (usually in cyanide) to expose the gold, and the reground material further cyanided separately or mixed back with the original slime.

6. Flotation (± gravity concentration and/or amalgamation) + cyanidation of concentrate. For clean ores with relatively high pyrite content, low content of valuable base metals (Pb, Zn, Cu), and gold largely associated with the sulphides. If coarse gold is present, amalgamation or gravity concentration with amalgamation of concentrate is inserted in the grinding circuit.

7. Flotation + cyanidation of tailing. Used for ores in which important amounts of gold are present in the nonsulphide minerals, and the sulphides are independently valuable or contain minerals harmful to cyanidation. Sulphide concentrate may either be smelted or treated (*e.g.*, roasting of arsenical concentrate) to render it amenable to cyanidation.

8. Flotation ± gravity concentration and/or amalgamation. Used for ores in which the gold is associated with sulphides and may not be separated from them other than by smelting, either for economic reasons (sulphides valuable and precious metals recovered from them as an incident to smelting), or for technical reasons (removal of cyanicides too costly; gold too fine, etc.). Use or non-use of gravity concentration depends upon the size at which sulphides free, and use of amalgamation is dependent upon size of gold, its surface character with and without grinding, the nature of the sulphide associates, and the quantity of gold thus recoverable.

In so far as any one principle can be said to be common to all of the great variety of flowsheets used on gold ores, that of taking out coarse gold as early and as quickly as possible is practiced, hence whenever coarse free gold is present some form of recovery at coarse-sand sizes is found; *vide* DOME, MCINTYRE, HOLLINGER, HOMESTAKE, etc.

Grade of ore and daily tonnage both affect milling methods through economic relationships. High-grade ores permit great latitude in the complexity of the method in that they will usually pay dividends with the most simple and inefficient mill, and will yield increased returns that will more than pay capital charges for almost any efficient refinement of treatment; they may be milled profitably at almost any daily tonnage up to the producing limit of the mine. Low-grade ores, on the other hand, must be milled at relatively high daily tonnages in order to spread fixed charges and superintendence over a sufficiently large weight of gold; the method of treatment must be both efficient and cheap.

Location of plant may be determinative as to process, in that freight on concentrate may be so high as to preclude shipment; in any case, it is an important economic factor in the choice between concentration and amalgamation or cyanidation, which latter methods produce bullion at the plant. Cyanidation of concentrate is, of course, an alternative.

Funds available for plant construction may cause concentration and/or amalgamation to be practiced where cyanidation is indicated from the standpoint of profitable extraction, because of the very considerable difference in first cost between the two types of plant.

Recoveries by concentration and amalgamation on free-milling ores range from 60 to 90%, according to amenability of the ore, and average between 70 and 75%; cyanidation yields run between 85 and 95 to 98%, averaging 90 to 95; flotation yields are usually between 80 and 90%, with recoveries between 90 and 95 not unusual, and cyanidation of nonrefractory concentrate will readily extract upward of 90% of gold in concentrate.

Marketing. Amalgamation and cyanidation yield bullion at the plant at a production cost from the crude concentrate (amalgam and precipitate respectively) much lower than that for smelting a concentrate produced by gravity concentration or flotation. Transportation of bullion per unit weight of precious metal is also much cheaper than that of concentrate.

Costs. Operating costs range from as low as 1.5 to 3¢ per ton for efficient high-tonnage hydraulicking or dredging to $2 to $3 per ton at small mills treating more or less refractory ores. Costs for large-scale milling involving fine grinding and cyanidation cluster around $1 per ton. Costs in very small, crude mills may run up to $3.50 or $4 per ton, even with simple flowsheets. Cost of plant ranges from $150 to $200 per ton of daily capacity for a simple amalgamation-gravity concentration plant built with cheap second-hand equipment and crudely housed to $2,000 per ton for a small, well-housed cyanide plant with all new equipment in a relatively remote location.

20. MILLING OF PLACER GOLD

Ore is sand or gravel plus the upper 6 to 12 in. of bedrock, with metallic gold. Heavy-sand associates of the gold (BLACK SANDS), in order of usual frequency of occurrence are: magnetite, ilmenite, rutile, garnet, zircon, hematite, chromite, olivine, epidote, pyrite, monazite, limonite, platinum, osmium, cinnabar, wolframite, scheelite, cassiterite, corundum, diamond, quicksilver, amalgam, galena (*IC 6786*). Gold particles occur in all sizes from nuggets weighing many pounds to colors running 200 to 1,000 to the cent. Ordinarily gold coarser than 10-m. is called COARSE, 10~20-m. is MEDIUM, 20~40-m. is FINE, <40-m. is FLOUR.

Methods of treatment differ principally because of mining problems, the requirements of tailing disposal, and the water supply rather than because of the concentrating problem. Gravity concentration of the crudest kind, with a size ratio between largest gangue particle and finest gold color of many thousand to one, is possible on account of the high specific gravity of gold. Sluices of some form (Sec. 11, Art. 26) are used in the great majority of cases, but shaking tables, fine jigs, and various (and frequently outlandish) modifications of these mechanical types are found in some plants. Necessary variations in preparation procedure are imposed by differences in size range of gravels and by the clay content, while size of gold and clay content influence the length and, to a certain extent, the design of sluices, particularly as respects riffling.

Essentially, a plant for saving placer gold comprises a disintegrating means to free the gold (equivalent to the crushing and grinding sections of the usual lode-mine plant), a means of rough concentration, a means of cleaning concentrate, and a means of tailing disposal. Since disintegration is often an incidental part of the mining operation and concentration is, as above noted, relatively simple, practice has tended to classify operations from the standpoint of the size of the deposit and the method of mining, rather than on the basis of the nature of the concentrating plant.

Panning and rocking are employed to work very small high-grade placers where water is scarce. (See Sec. 11, Art. 14.)

Shoveling-in is a long-tom or sluice operation (Sec. 11, Art. 26) applied to small, moderately rich deposits, with little water or little grade available. It comprises manual shoveling from the bed of gravel and lifting into a line of small sluices set high enough above bedrock to afford tailing disposal.

Maximum shovel lifts are 7 to 8 ft.; maximum efficient lift is 5 to 6 ft.; the lift is ordinarily broken, if the thickness of the bed of gravel averages more than 3 to 4 ft. Narrow sluices, 8 to 24 in. wide, are used, with shovel boards (one side of sluice raised) against which gravel is thrown. The best width of cut is about 6 ft. both sides. Stones larger than 5-in. are not shoveled in. Slope is 6 to 8 in. per 12-ft. box, if there is sufficient water. With insufficient water steeper slopes must be used and a screen box is placed at the head of the sluice to receive the feed. Water is fed into the box, oversize is forked out and clay balls disintegrated by puddling. A minimum flow of 15 to 20 miner's inches (170 to 225 g.p.m.) is required for a 12-in. box with a steep grade. The usual crew is 1 to 4 men. Capacity depends on the lie and character of the gravel, the amount of water, and the size and slope of the sluice. For mining detail see *Peele*.

Performances at several representative mines are given in Table 39. Average duty per man-shift, including cleaning bedrock, cleaning up sluice, and moving sluice line as necessary is between 3 and 4 cyd. Wimmler gives range in Alaska as 2 1/2 to 10 cyd. per 10 hr. with 3- to 7-ft. lifts.

Cost ranges from $1 per cyd. in easy gravel to $4 under difficult conditions.

Ground sluicing is a mining method which involves excavating and transporting gravel to the sluice line by water under ordinary stream pressures only. Ditches, wing dams, and the like are used to lead the stream from the face to sluice lines which start on bedrock. Stream water-action is usually augmented by manual work, or by a small giant (see ***Hydraulicking***), or by using the water in rushes (see ***Booming***).

The method is normally used in small operations where the size of the deposit will not justify more elaborate use of water, or where lack of available head or available capital prohibits use of pressure water. It is not effective with tight or cemented gravel. According to *Wimmler* it is best adapted to shallow gravels (<10 ft. thick) containing relatively coarse gold; it has been used on 80-ft. banks in exceptional cases. The best places for its use are benches and the upper reaches of creeks with steep grades.

Booming is a form of ground sluicing in which the stream water is dammed for a sufficient period to give flood rushes on release, with consequent greater excavating and transporting power of the available water.

Larger sluices are required to handle the floods. Duration and extent of floods are, of course, related inversely. Long floods of low intensity are the more desirable from the standpoint of gold saving; short, intense floods excavate and transport coarse gravel the more effectively. Automatic flood gates are commonly used, closed by a spring or weighted lever, and opened by a trigger mechanism actuated by floats, overflows from a full dam, etc. Boulders are removed separately by hand or by mechanical means such as derricks or draglines. For mining detail see *Peele*.

Performances in western United States in 1932 are given in Table 40. *Wimmler* gives 15 to 35¢ per cyd. for the usual cost range in Alaska, dropping to 7¢ for especially favorable conditions and rising to $1 when much shoveling-in is involved additionally.

a Includes mining.
b Exclusive ditch repairs, clean-up, supervision.
c Includes 2¢ for storage of tailing.
d Excludes general administration.
e Includes water for hydraulic elevator.
f Includes water for giant at Ruble elevator.

Hydraulicking is used when the deposits are large, lie well above the point of tailing disposal, and there is an abundance of water available under sufficient pressure. The method consists in cutting down the gravel and washing it through bedrock sluices and wing dams to the head of the sluice line by means of GIANTS or MONITORS, which are large (1- to 10-in.) nozzles operating under high pressure (50- to 400-ft. head). It competes with ***Dredging*** on a man-duty and cost basis, and is superior as a method with gravels containing much clay or many large boulders. Various types of elevators are used at the head of the sluice line when, as is frequently the case, the necessary slope and tailing-disposal room cannot be obtained otherwise. For mining details see *Peele.*

Hydraulicking requires a soft, even bedrock. The duty of water is usually stated as the number of cyd. of gravel that can be broken down and put through the sluice per miner's inch in 24 hr. This varies with the character of the deposit (depth, lie, tightness of gravel, size and number of boulders, character and grade of bedrock), the construction and arrangement of the sluice line (size, slope, riffling), the quantity of water available and the pressure, and the skill of the operator. The average for medium gravel, according to *Wimmler,* is 1 to 2 cyd., falling to 0.25 in unfavorable cases; if it is not necessary to elevate feed or to stack tailing, the duty rises to 3 to 4 cyd. on average gravel. Duty is low, if pressure is less than 80 to 90 lb. per sq in.

Sluices for hydraulicking are of large cross-section to handle boulders and the concomitantly large water flows. They must be made of heavy lumber, sturdily braced to withstand the shock of the rolling boulders (20-in. occasional max., if plenty of water is available; 6- to 8-in. common), and durably riffled. Block, rail, cast-iron and/or rock riffling are normally used in the main line, where wear is high; pole, angle-iron, and Hungarian riffles are used in the undercurrents. (See Sec. 11, Art. 26.)

Performances. Details of sluice lines and sluice operations are given in Table 41. Hydraulicking has worked gravels with 3¢ recoverable gold per cyd. at a profit. *Wimmler* reports average Alaskan costs as 30 to 35¢ per cyd. with a range from 6¢ to $1, but asserts that cost will not ordinarily fall below 20¢ for bench gravels or 25 to 30¢ for creek gravels. Cost of pump hydraulicking in the Nechi River section in Colombia (1938–1941) is reported to average 21¢ per cyd. *(143 #6 J 51).*

For water consumption see Sec. 11, Art. 26.

Mechanical mining is used for low-lying deposits and for high-lying deposits with insufficient water available for use as an excavating and disintegrating means. Under such circumstances transportation of feed and tailing becomes an important item, and disintegration and the separation of coarse oversize are thrown on the concentrating plant.

Methods involving mechanical mining may be classified into: (1) open-cut work; (2) drift mining; (3) dredging.

Open-cut gravel mining may employ any one of the usual animal or mechanical methods of excavation from slip scraper to power shovel, any of the ordinary methods of bulk transport, and the washing and concentrating plant itself may be either fixed in position or perambulatory. FIXED PLANTS have the advantages that crowding and limitation in size

Legend for Fig. 41:

1. Grizzly. Aperture depends upon the character of the gravel and that of the subsequent plant; it will be as small, down to 1 1/2- or 2-in., as will yield clean boulders as oversize.
2. Revolving-screen washer. Aperture and, consequently, the size for a given capacity depend on the method of concentration to follow.
3. Slime or other gravity concentrator, *e.g.,* a jig (Sec. 11).
4. Clean-up (see Sec. 11, Art. 26).

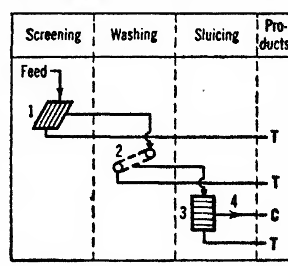

FIG. 41. Typical flowsheet for an open-cut or drift-gravel gold-washing plant.

and weight of apparatus are unnecessary, and that stability of setting and accurate alignment of apparatus are possible. The disadvantages are the probable necessity for mechanical transport of feed and tailing. MOVABLE PLANTS may have the advantage of standing on or over and discharging tailing onto worked-over bedrock, in addition to saving transport of feed, but they must be kept light in weight and are frequently correspondingly flimsy and expensive in upkeep; unforeseen rolls in bedrock may make moving and leveling-up slow and costly; storage must be sacrificed, with consequent delays and irregular feed to the concentrators, and water connections must be broken, extended and remade at each move. When used they should, of course, be started at a low point on the bedrock and be moved upslope to permit stacking tailing on worked-over adjacent land. A characteristic flowsheet is given in Fig. 41.

Performances at a number of plants in the western United States are given in Table 42.

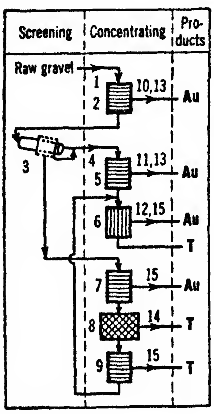
a Tailing pile. *b* To a crusher for crushed-rock market. *c* Boulders by hand. *d* Net. *e* Included in excavation.

It should be noted that scrapers are adapted only to large areas of shallow gravel, with few boulders, and either soft bedrock or, if hard, smooth and uncreviced. Under the best conditions power and labor consumptions are high, the set-up is expensive, cable wear and general repairs are high, and capacity is low. A SELF-DUMPING BUCKET on a carrier cable with a power hoist is useful on shoveling-in operations where sluice moving is undesirable. The COST is about the same or somewhat greater than for ground sluicing (*Wimmler*).

Drift-mining involves more or less elaborate underground excavation of gold-bearing gravel and, usually, the surface of the bedrock. Excavated material, delivered at the mouth of a shaft or tunnel, is transported to a washing plant similar to that used for open-cut material, except that where high-pressure water is available, disintegration may be done with a small giant in a wash box or on a grizzly, and that, with hard cemented gravel, mechanical crushing may be used (Fig. 43).

Vallecito Mining Co. Fig. 42 (*IC 6612*).
Location: Angels Camp, Calif.
Ore: Cemented drift gravel.
Assays: Feed, $8 Au per ton ($20.67 Au); tailing $0.17.
Capacity: 15 tons per hr.
Water: 500 gal. per ton gravel; about 300 gal. for sluicing, 200 gal. for transport of tailing.



Legend for Fig. 42:

1. 75-ton bin. Gravel washed out with water from a 2-in. line at 25 lb. pressure.
2. 16-in.×11-ft. sluice, Hungarian riffles. Slope, 2 i.p.f.
3. 3×18-ft. wash trommel. First 8 ft. blank with 4-in. angle-iron lifters. Discharge end concentric, 1 1/2-in. and 3/8-in. rd.-hole plate. Slope, 1/2 i.p.f., 28 r.p.m., 10-hp. motor.

Costs. *Wimmler* states that the cost of sluicing at Alaskan drift mines is 15 to 45¢ per cyd.

21. DREDGING

General. Dredges are a combination of an elevating excavator, a gold-concentrating plant, and a tailing-disposal plant, all mounted on a barge. They float in natural bodies of water, or in self-excavated ponds which they enlarge ahead and fill in behind as they work successive horizontally parallel substantially vertical slices of gold-bearing ground. They are used for gravel deposits, such as those in wide valleys, that lie below any level available for the gold-saving plant. The gold in such deposits is usually fine. *Janin* reports the following sizing test on Oroville gold:

Screen, mesh......	>60	60∼100	100∼120	120∼150	<150
Weight, %........	58.1	15.3	2.9	2.4	21.1

and states that it is about the same size in other California dredging fields, with only an occasional nugget ranging in value from 50¢ to several dollars ($20 gold). He gives also a sizing test on Montana gold that falls in the same size range. The most desirable type of gravel is one that contains 50% upward of $<1/2$-in. fines with clean coarse cobbles and a few medium-size boulders to aid in disintegration by tumbling action in the screen. Efficient dredges for inland gravels are large and costly apparatus ($50,000 to $1,000,000) and are used, therefore, only when the gravel deposits are large. Operating costs are, however, almost unbelievably low (2.5 to 15¢ per cyd. excavated) and, under normally favorable conditions, recoveries are high, so that excellent profits can often be made out of gravels carrying less than 10¢ recoverable value per cyd. ($35 gold), provided the deposit is sufficiently large to spread amortization thinly. An average of 60 dredges worked in California alone over the years 1905 to 1915; about 20 more were operating by 1914 in Montana, Idaho, and Colorado, and 50 to 60 in Alaska. From 1922 to 1932 the average annual recovery on California dredges was from 8 to 10.7¢ per cyd.

Types of dredges. Dredges are classified on the basis of the excavating and elevating mechanism, and of the gold-saving and tailing-disposal devices. The relative simplicity

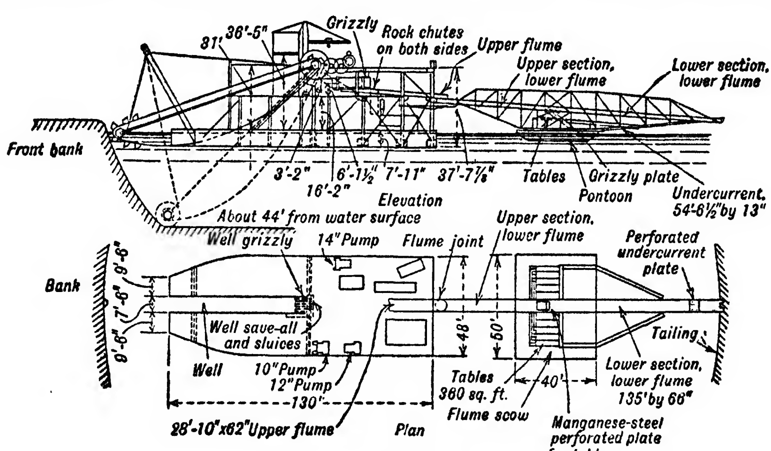

Fig. 44. Sluice dredge.

and cheapness of SUCTION DREDGES have caused the construction of at least one of this type in most of the placer gold fields of the earth, but their record of nonsuccess is almost perfect. POWER SHOVELS and CLAM-SHELL or ORANGE-PEEL BUCKETS as dredge digging mechanisms have had limited success in small shallow nonbouldery deposits with soft bedrock. But as a practical matter, the continuous bucket line carried on an endless chain suitably mounted is almost universally employed as the digging and elevating mechanism today. The SIZE of the dredge is indicated by the capacity of the individual buckets. The usual range is 3- to 16-cu. ft. One of 20-cu. ft. has been built. Digging depths average 30 to 40 ft. below pond level, with 120 ft. the maximum reported; stackers on large dredges may deposit 100 ft. above pond level. Digging capacities are given in Table 43. *Wimmler* states that the capacity of Alaskan dredges ranges from 20 to 60% of the product of bucket capacity and buckets per min., and averages 40 to 45%. Running time is 75 to 80%. The

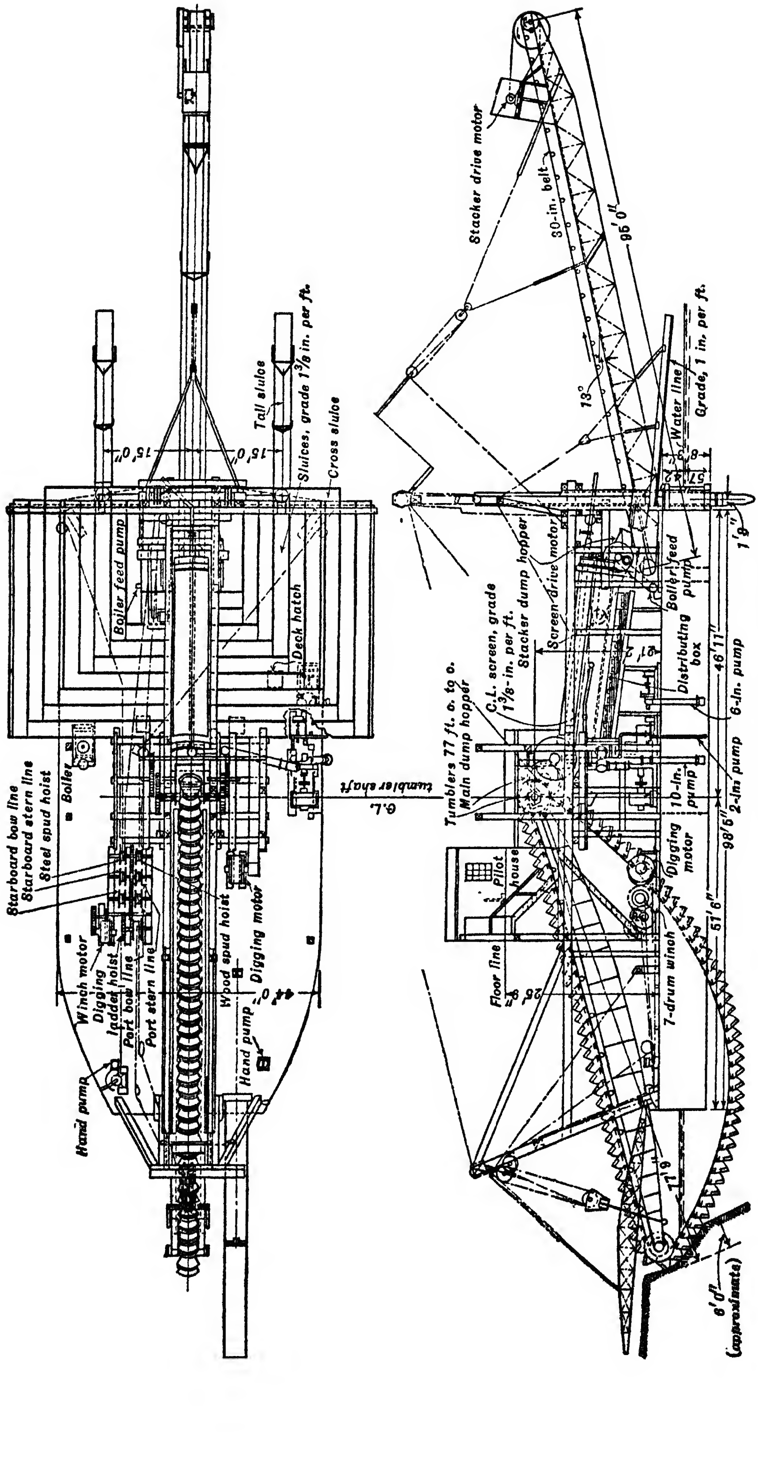

FIG. 45. Stacker dredge (*IC 6659*).

bucket line, its drive, and the support of the loads that it imposes are by far the most expensive parts of a dredge, both in first cost and in operation. Details are beyond the scope of this book. See *Peele;* Gardner and Johnson, *IC 6788;* Jennings, *Bul 121 USBM; Janin.*

Table 43. Digging capacities of bucket dredges (*56 CMJ 106*) *a*

Buckets, cu. ft...	3	4	5	6	7 1/2	10	13 1/2	15	18
Thousands cyd. per 24 hr.....	2 to 2.5	3 to 3.5	3.5 to 4	4 to 4.5	5 to 6	7.5 to 8.5	8.5 to 10	10 to 12	12 to 15

a Capacities are based on average ground 30 to 35 ft. deep, and 80 to 85% operating time; for easy ground increase 50 to 100%; decrease up to 50% for hard ground.

Principal gold-saving device on most gold dredges is some form of SLUICE, supplemented by AMALGAMATION. JIGS are used as auxiliaries on a number of dredges and as the principal gold saver on a few. They are particularly advantageous if the gold is fine or rusty or locked. A sluice or flume dredge (Fig. 44) is one in which the sluice serves also as the device for tailing disposal; its use is limited to relatively shallow deposits (12 to 15 ft.). A stacker dredge (Fig. 45) is one utilizing an elevating conveyor to dispose of the coarser tailing. Stacker dredges preponderate greatly on account of superior flexibility in tailing disposal and the greater sluice area possible. Sluice dredges are, and practically must be, used when the gold is coarse and nuggety, necessitating treatment of material up to 3- or 4-in. size.

Gold-saving plant on dredges comprises essentially a screen so operated as to disintegrate the gravel, if necessary, and to rough out coarse gold-free gravel; a sluice line to rough out and discard the bulk of the intermediate and fine waste in the screen undersize; a strake (unriffled main sluice) to effect primary cleaning of the rough concentrate from the main tables; a long-tom or small sluice for recleaning; and amalgamation, sometimes preceded by screening out coarse sand, for final separation.

Ultimate ratio of concentration in gold dredging is almost unbelievable. In a comparatively rich gravel, say one carrying 50¢ per cyd. of recoverable gold (at $35 per oz.), the volume of gold is only 1/40 cc. and the volume of barren material to be rejected is 770,000 cc., giving an ultimate volumetric ratio of concentration of roughly 30 million : 1. The screen roughs out approximately half of the tailing in normal California gravels; the table riffles will hold about 350 cu. ft. of concentrate, which constitutes, say, a 600 : 1 ratio. Clean-up on the tables involves about 5 : 1 reduction in bulk. A small sluice treating this material will cut it down 200 to 500 : 1. Screening the concentrate makes about a 2 : 1 shrinkage in bulk, leaving the balance for amalgamation.

Detail of Gold-Saving Plant

Hopper. The bucket line discharges into a hopper, which constitutes a feeder for the screen. With cemented and clayey gravels disintegration starts in the hopper through the medium of a high-pressure jet or monitor played on the material therein.

The hopper should fit with minimum clearances around the sides and front of the bucket line, be fitted with adequate splash boards, and the lead-out chute should be so placed as to maintain a layer of gravel on the bottom to resist wear. Worn bucket pins are commonly used for liners. With sticky gravel, high-pressure jets must be used to discharge the buckets and wash off the sides, in which case the splash boards must be carried over the front and as far as possible down the ends of the hopper. On NATOMAS No. 8, the use of 90-lb. water on the head of the digging line increased digging capacity 50 cyd. per hr. and saved digging power.

Grizzly. With much coarse, bouldery material and a deep pond, a grizzly is placed over the feed hopper; the oversize therefrom passes over the sides of the boat.

Screen is placed in the upper part of the boat superstructure to take the discharge of the bucket line. Screens are almost universally of the rotary type. Shaking screens have been used, but they are not effective disintegrators and are structurally bad on account of the heavy oversize burdens that they must carry.

Rotary screens for dredges are cylindrical, of roller type (Sec. 7, Fig. 29), and of exceptionally heavy construction. The essential structural elements are the frame, the support, the drive, the covering, and the housing.

Frame consists of two circular end castings with a plurality of longitudinal members, usually six, connecting them and forming with them a symmetrical polygonal truss of diameter somewhat greater than that of the screening surface. In the older forms the longitudinal members were usually heavy angles bolted to the heads and braced against the driving torsion, either by heavy gusset plates or by lacing adjacent angles together to form girders. In modern forms welding is substituted for bolting, and some manufacturers have substituted tubes for the angles. The rings to carry the screen plates are fastened at suitable intervals to the longitudinal members; when welded joints are used these rings add great additional stiffness to the frame.

Support must accommodate to the reception of feed, the discharge of undersize and oversize products, and admission of wash water; and must take up the thrust incident upon setting the frame axis at an angle to the horizontal. This requires that the feed head, at least, be open and, therefore, roller-supported. The discharge end may also be open, in which case roller support is necessary here also; or it may be a circular plate, spaced far enough from the end of screen surface to permit discharge of oversize between it and the screen lip, in which case this end is usually supported on a bearing. Tires and rollers are of alloy steel; when tire support is used both ends, a thrust roller must also be provided. Splash rings are used to protect both tires and rollers from grit, and water sprays are used at the rollers additionally to eliminate grit that has evaded the splash rings. Support should be on steel; alignment cannot be maintained on wood.

Drive is either by roller or by gear, and, in the former case, may be at either end. It is more accessible and less subject to splash when at the lower end, but roller traction is less and torsion is greater. A single drive roller, placed either directly under the axis or just off center, is usually considered best; uneven wear occurs when two drive rollers are employed. Drive gears are beveled, cut, carefully faced, and truly bolted to the drive head. The drive problem is similar to that with tumbling mills (Sec. 5, Art. 4).

Speed ranges from about 160 f.p.m. peripheral for small screens to 200 f.p.m. for large.

Screen plate is made of high-carbon steel with drilled holes or of cast manganese steel with cast holes. Plate is usually from 3/4 to 1 in. thick. BRIDGES (metal between holes) vary according to requirements for total aperture area, but rarely are less than the thickness of the plate. Manganese-steel plates normally give two to three times the wear of high-carbon steel. Holes taper outwardly about one in four. Segments are rolled or cast to the proper radius and bolted to the longitudinal members. LINERS for blank jackets are best made of castings about 6 in. wide, of the thickness desired but not less than 1 in., and of a length permitting relative ease in handling. LIFTER BARS are usually rectangular, with sufficient base to guard against overturn; they are spaced 9 to 12 in.; projection is normally too little to effect cascading. Bars are shifted when the intervening screen wears. Peripheral wearing plates at the retarding rings save the screen plate from the excessive wear at these points.

Wash water is introduced through nozzles from a header which may run the length of the screen inside, or across both ends. With gear drive the bearing may be made of trunnion type to permit entry of the SPARGE PIPE (spray header) from the discharge end, which removes obstruction from the feed end. Longitudinal headers have 1- to 2-in. nozzles spaced 12 to 16 in. Smaller nozzles clog with debris from the pond, and likewise decrease impact of the stream because of the tendency to spray the jet. End-placed nozzles are usually 2-in. and differently directed to distribute the washing effect. They are less effective than those longitudinally placed, but offer less obstruction to repair work. WATER PRESSURES are ordinarily between 25 and 75 lb. per sq. in.

Slope of screen is usually about 1 1/2 in. per ft.

Distributor. The distribution of screen undersize to tables or jigs is one of the important elements in dredge construction and operation. The principal desiderata are: (*a*) equal loading of tables, having consideration for gold content, volume of gravel, and area and length of table; (*b*) uniformity of feed, both as to solid and water tonnages and to particle sizes; (*c*) accessibility; (*d*) simplicity of operation; and (*e*) minimum head loss. The problem is generally considered less serious in feeding tables than in feeding jigs. The simplest form of distributor comprises a series of transverse partitions in the bottom of the screen housing, with spouts from the compartments thus formed discharging alternately to port and starboard. A slightly more elaborate variant of this is a longitudinal divider, usually shifted somewhat toward the upcoming side, which is designed to halve the discharge at any longitudinal section and permit closer spacing of the outlet spouts on each side. Spacing of the transverse dividers is proportioned so as to give the desired tonnages, bearing in mind that discharge from the screen decreases, nonuniformly but regularly, from head end to discharge end; and that the capacity of the following concentrators is dependent, more or less according to type, upon particle size of feed. With distributors of these general types, without gates on the discharge spouts, there is no method of regulating feed rate to different following apparatus except by major structural changes; they are simple and give minimum headroom loss but are substantially inaccessible, and completely dependent for uniformity on the uniformity of the gravel and water fed to the screen. By providing weir overflows from compartment to compartment, and by gate controls in the discharge spouts, some control of distribution may be effected, with corresponding improvement on the score of uniformity, but the improvement is not great. Romanowitz and Sawin (*26 #12 MCJ 23*) state that recent decreases of some 33% in sluice area provided on modern dredges flows from better distribution, particularly as to size and pulp dilution.

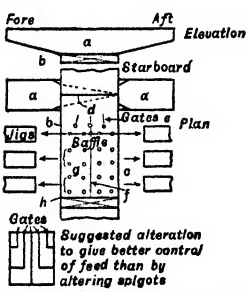

FIG. 46. Distributor for jig feeding.

When jigs are used, it is essential to optimum operation that the feed enter uniformly distributed across the width of the bed, and that the size of feed particle and the feed-pulp

dilution remain approximately constant. To effect this, there must be provision for controlled dewatering and some regulable device for controlling the direction and thereby the quantity of solid flow. Such a device is shown in Fig. 46 (*47 MM 119*), in which the screen hopper *a* slopes both ways to a discharge spout *b* near the longitudinal center, whence the pulp falls into a transverse settling box *c*, the amount of pulp going to port and starboard being controlled by a pivoted gate *d*. Gates *e* control flow along the settling box; a center baffle *f* prevents overloading fore or aft sides with variation in longitudinal tilt of the boat due to changing position of the digging ladder; and spigots *g* with variable aperture control discharge. A weir overflow *h* takes care of excess water, and, in combination with spigot diameter, determines the minimum size sent to the jigs. This arrangement is reasonably simple, is accessible, tends toward uniformity of feed, gives straight flow to the jigs with corresponding tendency toward uniform distribution across the width, but does lose headroom, and necessitates some re-elevation of feed to secondary jigs.

On the De Lamar dredge (*26 #3 MCJ 22*) the distributor was built like a Jones riffle (Sec. 19, Art 3) 28 in. wide by the length of the screen (28 ft.), with 6-in. slots discharging alternately on opposite sides. For other methods see *Janin*.

Design of screen. H. A. Sawin (Sales Eng'r, Yuba Mfg. Co., *PC*) states that his company has no general rules for design, but that the factors that must be considered are: (*a*) degree to which the gravel is cemented, (*b*) the amount and character of clay, (*c*) the percentage of fines, (*d*) the size and quantity of cobbles and boulders, taken in connection with the depth of the pond, and (*e*) the character and size of the precious metals. The more firmly the gravel is cemented the more tumbling it must be subjected to in order to effect disintegration; experience indicates, however, that length rather than diameter is the important factor in this respect. Clay requires puddling, which is effected by hold-back rings; a blank section at the head with hold-back ring may be desirable, if clay is in large lumps. The percentage of fines and the size of the gold particles govern perforated area and minimum diameter of perforations; Table 44 indicates that about one cyd. per hr. per sq. ft. of perforated area per in. of aperture is the usual allowance for loose and relatively clay-free gravels with a normal percentage of fines, while the yardage drops to half or less this with hard, clayey gravels where disintegration requirements become important. Apertures of $^3/_8$- to $^5/_8$-in. are usual for granular gold; the figure rises to 1-in. upward with nuggety gravel. With many large boulders, particularly in shallow ponds where dumping of boulders over the side would risk shoaling the boat, the boulders must be passed through the length of the screen and up the stacker. In this case screens are provided with perforated liner plates, installed in register with the perforations of the jacket; these have the effect of doubling the jacket thickness.

Table 44. Sizes of dredge screens (*After Janin*)

Bucket capacity, cu. ft.	3	5	7	9	16
Screen: diam., ft.	4	5	6	7	9
Length of perforated section, ft.	15	20	25	30	38
Motor, hp.	20	25	35	45	75

M. F. Keese (Bucyrus-Erie Co., *PC*) states that they design screens for the largest probable amount of undersize, and that the formula $D = 3.3\ C^{0.6}$, where D = diameter of screen in inches and C is total feed in c.f.m., holds. Length of perforated section is made approximately four times diameter.

The biggest screen reported was 9×50-ft., weighed 110 tons, and was driven by a 100-hp. motor.

If gold is coarse, larger apertures must be used, and less screening surface is necessary. Frequently the holes at the head end are smaller, to distribute the load to tables more evenly. One dredge used 4 sizes of holes with satisfactory results. A Colorado dredge used one ring of coarse screen at the lower end to make certain that no nuggets slipped by, sending this fraction to a specially riffled sluice.

With much clay, disintegration becomes an important factor; a part of the length is blanked off and an annular ring placed at the lower end of it for tumbling the material in water; lifter bars cover a part of the screen surface, necessitating greater length to maintain total aperture area; hold-back rings may be put in the screening section also, where they have the effect of thickening the bed, with consequent decrease in screening rate per unit area of perforated surface. At Gold Hill Dredging Co., Loomis, Calif., gravel particularly hard to disintegrate is sent to a 10(diam.)×18-ft. ribbed cylinder preceding the screen.

Step screen is a rotary with several sections of decreasing diameter from feed to discharge end. It weighs less than the straight cylindrical rotary, and the steps act as hold-back rings with no fall on the downstream side, thus eliminating considerable wear. The concentration of weight at the head end gives more relative traction for head-end drive and less torsional strains on the screen frame. There is some saving in headroom. On the other hand, screen plates are not interchangeable, the structure is more complicated and less rigid than the one-diameter frame, and either more load is put on head-end tables or head is lost in distribution.

Shaking screen is used on some dredges. The 7 $^1/_2$-cu. ft. dredge at Adelong Gold Estates near Bright, Victoria, N. Z. (*27 CEMR 237*) uses such a screen, 8 ft. 9 in. wide × 35 ft. long, with 4-rod sus-

pension driven by an eccentric mounted above the transverse centerline of the screen, with two eccentric rods attached near each end of the frame. Slope of screen is 1 1/4 in. per ft.; speed, 70 @ 8 3/4-in. r.p.m. Two @ 11-in. longitudinal spray pipes are placed 4 ft. apart, with 1-in. holes 10 in. apart in staggered rows. Good disintegration is reported.

Tables are shallow, relatively steep sluices (slope from 1 to 1 1/2 in. per ft.) arranged in side-by-side banks on both sides of the boat. See Figs. 45 and 46 for two arrangements. Some form of Hungarian riffle (Sec. 11, Art. 26) is almost universally used. The tables are usually single-deck and of wood construction on the smaller boats (up to 7 1/2-cu. ft.); they are double-deck, steel on larger boats. Quicksilver is invariably used, special amalgam traps and riffles being provided on some dredges.

Average MERCURY CHARGE is close to 1 lb. per 2.5 to 3 sq. ft. of table area; LOSS ranges from 1 to 5%, averaging between 2.5 and 3%; it is highest on clayey feeds. TABLE AREA provided on some 50 dredges ranges from 6 to 17 sq. ft. per hourly cyd., or 150 to 400 (aver. 250) sq. ft. per cu. ft. of rated bucket capacity, according to the size and character of the gold. Keese (*loc. cit.*) states that Bucyrus usually allows approximately 8 sq. ft. of riffled area per c.f.m. to the dredge screen. Area may be approximately doubled on a given boat by installing double-tray riffles in the sluices. NATOMAS tests (*IC 6788*) indicate 90 ft. minimum LENGTH. Standard California WIDTH is 32 in. (*56 CMJ 106*). *Janin* estimates that 35 to 60% of the material dredged is undersize of the usual stacker-dredge screen; Lewis (*56 CMJ 106*) gives 50% <1/2-in. as an average for California gravels; it may run up to 80% on sluice dredges. SLOPE of transverse tables averages about 1 1/4 in. per ft.; longitudinal about 1 1/8 in. FEED RATE and WATER QUANTITY are dependently regulated to keep the sand between the riffle cleats fluid, on the well-substantiated theory that more gold is lost by inability to penetrate the inter-riffle spaces than by carriage in suspension. WATER is provided in such a way as to permit individual regulation of the supply to different tables. Sawin (*loc. cit.*) states 10 to 12 parts of water to 1 of fines by weight to be the customary provision with normal gravels; double this for very clayey gravel. Heavy wire net is placed around the high-grade parts of the sluice lines to prevent pilfering. Sawin (*loc. cit.*) states that sluice or table width rather than area is the important factor in table design, and that YUBA No. 20, designed on this principle, riffles only the athwartship tables, which discharge into two unriffled longitudinal sluices, the sole function of which is to discharge tailing. Distribution is arranged to permit athwartship tables well aft the end of the screen. This arrangement eliminates the practice of discharging 2 or 3 athwartship sluices into the longitudinal, with consequent overloading of the latter.

Sluices on sluice dredges are 24 to 48 in. wide, 60 to 100 ft. long, slope 1/2 to 3/4 in. per ft., and are more coarsely riffled than tables, *e.g*., 2- to 3-in. angles. Undercurrents are usually used as supplements. See Sec. 11, Art. 26.

Save-all is a small sluice placed under a grizzly (about 2-in. average aperture) in the well of the boat. It receives the undersize of the spill from the head of the bucket line. Slope must be steeper than the main tables since more material must be handled per unit area and feed is coarser. GRIZZLY should be easily maintained, *e.g.*, individual bars in a comb rack. The entire save-all construction is protected against a bucket-line fall by heavy transverse girders. The save-all may recover much or little, depending upon the ladder slope, bucket and hopper design, the character of the gold, etc. Lewis (*loc. cit.*) cites 4 to 400 oz. recovery in the same length of time on different boats.

Jigs replace tables in some dredges and are used on others to supplement them. Their use started on tin dredges. Both pulsating and reciprocating types are used. They are especially effective for very fine gold, gold that is hard to amalgamate, or gold associated with heavy-mineral sands which pack in riffles.

On a NATOMAS dredge jigs (Sec. 11, Arts. 7 and 8) were placed in the first four table lines on both sides of the boat. These jigs made about 40 tons concentrate averaging $0.75 to $1.50 per ton per day from each side of the boat, constituting about 75% recovery on jig feed and a saving of 1 to 2¢ per cyd. of original feed to the boat. Concentrate was reground in Hardinge pebble mills and amalgamated.

On the DE LAMAR dragline dredge (*26 #3 MCJ 22; 139 #7 J 60*) <1/2-in. gravel at the rate of 12 to 24 cyd. per hr. with 2,950 g.p.m. of water was sent to 2 @ 4-cell 42-in. Placer jigs (Sec. 11, Art. 7) in parallel (one each side). Stroke, 1 3/4 in.; 120 r.p.m.; bed 3/16- and 1/4-in. steel shot, and coarse concentrate allowed to build. Rough concentrate (70 : 1 ratio of concentration) from both sides was combined and dewatered in a 2×5-ft. drag classifier (slope 45°, 47 f.p.m.) and sent to a 2-cell 12×12-in. Crangle hydraulic pulsator cleaner jig, bedded with 1/4- and 3/16-in. shot and coarse concentrate and making 200 pulsations per min. Ratio of concentration on these jigs was about 1,000 : 1. Concentrate passed continuously to a Titan amalgamator (Sec. 14, Art. 7), and the tailing thereof to 1 @ 1-cell 12-in. Crangle jig which recovered a small amount of rusty gold and amalgam and discharged tailing to shipping concentrate. Tailing from the cleaner jig passed to a dewatering cone and thence to a 4-cell @ 9-in. Placer-type scavenger jig making 240 @ 1-in. s.p.m., bedded with 1/4- and 3/16-in. shot, coarse garnet, sulphide, and cassiterite concentrate. The jig made a concentrate, mostly garnet, which, with that from the safety jig, assayed more than $40 per ton. Use of this cleaner scavenger was novel on this boat. Cost of jig operation (1937) was 6.7¢ per cyd.

The jig installation on this boat replaced sluices which had not made satisfactory recovery on account of the considerable amount of old amalgam and mercury from the gravels from prior working.

The KISTER dredge at Oroville (*Min. Wld., Seattle, 9/39*) was equipped with jigs after the usual sluice equipment had failed to recover gold indicated by sampling. The equipment comprised 2 @ 2-cell 42-in. rougher jigs each side with tailing discharged over 12 ft. of riffled sluice to the tail sluice. Com-

bined rough concentrate was elevated by pump, dewatered in a pyramidal sand tank and fed to 2 @ 24-in. 2-cell Pulsator jigs, discharging tailing over burlap tables, and concentrate which was amalgamated continuously in a Titan amalgamator, the reject from which passed to a 2-cell 12-in. Pulsator jig which discarded tailing over burlap tables, and returned concentrate to the amalgamator.

Sawin (*PC*) comments that while there are placer sands that are better handled on jigs than tables, the former have the present disadvantages that they require a different skill to operate than is usually found around placer fields and that they therefore require more labor; that they lose efficiency when under- and overloaded; that they develop dead spots which, of course, decrease efficiency; and that, because of their sensitiveness to load conditions and the usual ignorance at the time of dredge design as to the exact fraction of the daily yardage that will go through the screen, design involves a correspondingly large element of guesswork. Jigs require less water than sluices. Plunger jigs on VICTORIA, N. Z., gravels have given much higher recovery than sluices, probably on account of the fineness of the gold (*31 CEMR 5*). Arguments put forward in favor of jigs are: Once a particle is caught in a jig it cannot thereafter be lost, whereas it may be washed or splashed out of a riffle. A jig saves more black sand; if black sand is used as an index of efficiency, jigs far surpass riffles. Final concentrate from jigs contains no light sands; there is considerable in riffle concentrate, making a greater quantity of concentrate to clean. Riffles must be shut down for a clean-up; jigs discharge while operating. Jigs are particularly advantageous for clean-up concentration. It is to be noted that the high ratio of concentration in roughing both on jigs and tables is bad practice generally, and that improvement in placer recoveries is most likely to come by way of a treatment scheme that breaks the present roughing step on screen undersize into at least two steps. A start in that direction is made on the new NATOMAS dredge (*A TP 792*), which has 8 @ 42×42-in. Bendelari jigs each side of the screen and makes rough concentrate at a 25 : 1 ratio of concentration, tailing going to sluices for scavenging while concentrate goes to cleaner jigs and thence to grinding and amalgamation. Cleaner-jig tailing goes to mercury riffles and thence to waste. The jigs treat 12 cyd. per hr. each. The latest YUBA (California) dredge has all jigs except for a short sluice following the screen.

Flotation was tried by Leaver and Wolf (*A TP 792*) on a variety of products as follows: Backwash sands assaying 17.5¢ per ton from TRINITY DREDGING Co.; original gravel, assaying 49¢ per ton; pond slime, $1.12 per ton; fine-sand portion of tailing, 38¢; cemented boulders after grinding and screening, 52¢; sand-bucket tailing, 39¢; <6-m. material from sand-bucket tailing, 22¢; tailing from belt sluice, 33¢; all from GOLD HILL DREDGING Co.; quartzitic portion of tailing @ 91¢ and regular tailing @ 9¢ per ton from FAY dredge; tailing from riffles re-treating jig concentrate, assaying 39¢, from NATOMAS; and waste backwash from YUBA No. 17 assaying 14¢ per ton. Recovery ranged from 12% on GOLD HILL pond slime to 76% on the TRINITY material, using amyl xanthate, Aerofloat, and pine oil or cresol. Ratio of concentration ranged from 35 to 50 : 1. The results were not promising; the effect of return of reagent in recycled pond water might well harm amalgamation.

Clean-up interval varies with the character of the gold and the gold content of the feed. On large dredges it is 7 to 10 days for the main tables, with the side sluices cleaned up every other time. The time required for a clean-up is 4 to 8 hr. The method varies in detail, but essentially involves preliminary concentration to about 20 to 25% of bulk in the sluice, stripped progressively from the head end, and final clean-up in a long-tom or small sluices fitted with some form of screen over fabric. At YUBA the sand concentrate is screened at 8-m. and the undersize, in charges of 1,000 lb., with 20 lb. Hg, 1/4 lb. KCN, and 80 gal. water is milled 2 hr. in a barrel and then washed to the clean-up sluice. The cyanide aids amalgamation and prevents flouring. With it there is a gain of about 10 lb. of mercury per 100 tons of sand against a loss of 20 lb. without it. At RUBY a special clean-up box 3 ft. long by 18 in. wide by 15 in. deep, sloped 1 1/2 in. per ft., is divided into four compartments by downwardly projecting baffles extending to within 3 in. of the bottom. Three upwardly projecting 3 1/2-in. baffles, placed one at the lower end and one in each of the two center compartments form mercury traps. All rough concentrate from the main sluice is fed through this clean-up box, and in flowing under the downwardly projecting baffles is forced into the mercury pools. Tailing passes to the main sluice through a small sluice fitted with expanded metal on coco mat.

Belt width, in......	20	24	30	36	42

Stacker is a belt-conveyor on an inclined boom projecting 50 to 250 ft. upward from the rear of the boat. It handles screen oversize and may be fed with deslimed sand tailing elevated from a sump tank receiving part or all of the sluice tailing. General considerations governing conveyor design are given in Sec. 18, Art. 6. Usual practice when tonnage is the dominant factor is summarized in Table 45; when size governs, see Table 46. Speed of belts in Table 45 should be about 400 f.p.m.; those in Table 46 should

be as low as possible to prevent jar, wear, and spill. With large boulders, finger gates are provided to prevent roll-back. Slope should be as low as possible to prevent loss of capacity and high wear due to slip, and should not exceed 22°. Slip-back increases with the wetness of the gravel. Two stackers lower the tailing pile. Length of stacker on the YUBA Hammonton dredge is 275 ft.

Fine tailing is usually discharged directly from the main sluices into the pond, but where it is desirable to control the sand content of the pond they are discharged into sumps at the rear of the hull and elevated thence by bucket elevators or sand wheels onto the stacker belt.

Yardage is a highly uncertain figure in all reports of dredge operations, since there are no means of direct measurement available. Methods of estimate range from bucket counting to elaborate surveys. The bases of all survey measurements are area dug and mean depth, but since the latter figure normally requires integration of depths read on the digging ladder at unspotted points on unsurveyed swings, the "average depth" becomes little more than a guess.

Power consumption varies, of course, with the character and lie of the gravel. *Janin* gives figures for 10 NATOMAS dredges ranging from 0.62 kw-hr. per cyd., dredged from a bank 3 ft. above water and 23 ft. below, to 2.4 kw-hr. for a bank 10 ft. above water and 53 ft. below. The figures for 4 CONREY dredges (Montana) range from 1.09 kw-hr. for 45 ft. average depth to 1.55 for 28 ft. average depth. YUKON GOLD Co. dredges at Dawson consumed an average of 1.0 kw-hr. per cyd. over a 3-yr. period. At OROVILLE the consumption on one dredge ranged from 0.79 to 1.36 kw-hr. according to the character of the gravel. From 35 to 50% of the total power is used on the digging line.

Water consumption varies with the character of the material and the type of dredge. *Janin* reports a range on stacker dredges from 1,400 gal. per cyd. dug with loose unconsolidated gravel to 2,800 gal. on sticky clay at NATOMAS, with an average of about 1,900 gal. per cyd. dug for 12 dredges reporting. This figure will just about double if high-pressure water is used to clean buckets. Gal. per min. per sq. ft. of table area ranges from about 2 to 5. On flume dredges in ALASKA the circulation is about 3,600 gal. per cyd.; the CONREY flume used 4,800 gal. new water; requirements for NATOMAS dredges in 1913 were 100 miner's in. per dredge; 50 to 70 in. for a 5-ft. boat at CALAVERAS; 350 in. for an IDAHO dredge working upstream on a 4% grade. In very clayey gravel the new-water requirements increase as well as the circulating-water requirements (for bucket cleaning and disintegration) on account of the fluid-density increase in the pond. This high-density muddy water tends to suspend and carry away fine gold from the face of the bank and to carry gold in suspension over tables or jigs. Lewis (*56 CMJ 106*) reports one pond in which the slimy water carried 50¢ gold per ton. *Wimmler* states that average Alaskan new-water requirement to keep down pond density is a continuous flow of 35 to 50 miner's in.

Recovery by dredging is not really known on account of substantially insuperable difficulties in sampling. Roughly it probably ranges from 50 to 90% of the gold content of the deposit as indicated by careful drill-hole sampling. Losses occur in bedrock, gravel undug or spilled, gold in suspension in high-density pond water, gold sticking to undisintegrated clay, large nuggets in screen oversize, and fine and rusty gold that escapes the tables.

Comparison of dredges. Sluice dredges are inferior to stacker dredges for saving fine gold on account of the relatively high velocity current required in the necessarily short main sluice to carry 3- or 4-in. gravel, and the restricted area of undercurrent tables available Other DISADVANTAGES are: the low elevation at which tailing is delivered, which difficulty becomes aggravated when working downstream on gravel which increases in depth downstream; the large pond that must be maintained, and kept open in freezing weather; and the fact that, at the start of operation, tailing may need to be discharged onto virgin ground and must, therefore, be reworked to reach that ground. ADVANTAGES, other than the certain passage of coarse gold to the sluices, are elimination of the relatively costly stacker, and a certain amount of resoiling effected by discharging fine tailing on top of coarse as the boat moves forward.

Costs are difficult to estimate and published costs even more difficult to compare accurately. There is no direct measure of yardage handled. The product of number of buckets by rated bucket capacity may exceed actual yardage by 500%; the excess for all NATOMAS dredges for 1913 was 100% as against estimates based on careful surveys of yardage in place. Bookkeeping methods vary widely, particularly as to items of depletion, depreciation, distribution of major repairs, taxes, and litigation, etc. Physical conditions of the deposit are greatly different for different dredges and may change abruptly in the progress of a given dredge. *Janin* reports a range from 200 to 80 cyd. per hr. on the same dredge on the same property due to changes in digging conditions. Low operating costs per cyd. attained by speeding up the bucket line may actually represent poor economy by reason of loss of gold at the foot of the digging ladder and further loss on overcrowded tables. Operating time is an important element; 80 to 85% is about the maximum average.

Gardner and Johnson (*IC 6788*) give an average operating cost figure (exclusive of taxes, insurance, and capital charges) of 5.1¢ per cyd. for all states for 1931 against 4.2¢ for 1914. These figures together with those in Table 47 for 1932 and the following detailed figures excerpted from *Janin* for the period prior to 1918 constitute a basis for estimate. CONREY No. 3: 5.4¢ per cyd. working downstream at 163 cyd. per hr.; 4.9¢ working upstream at 204 cyd. Aver. of four CONREY dredges: 5.9¢ operating,

Investigation of dredging possibilities. *Janin* lists the factors to be investigated and considered before determination on this score.

1. **Gold**: quantity, character, and distribution. Recoverable gold is the important quantity. If particles are light, thin, scaly, or rusty they will be hard to amalgamate and dredge loss will be high. Rusty gold may be expected in tropical regions. Pan, rocker, or long-tom tests on representative test-pit or drill-hole samples should prevail. If bedrock is hard and rough or shattered, recovery will be low; increasingly so as the gold is concentrated near it.

2. Gravel: depth, character and quantity. Very shallow deposits are expensive on account of frequent moves and shallow ponds. Very deep gravels require heavy digging machinery, much power, and delays are relatively high, if any unusual difficulties are encountered. Twenty to 40 ft. is probably the most favorable thickness range, but depths greater than 100 ft. are being worked. Banks high above pond level require a monitor to break down ahead of the dredge to guard against slides and this cutting involves both additional labor and power as well as loss of a certain amount of gravel and fine gold that runs into the pond back of the current cut of the digging line. Cemented gravel is hard to dig and to disintegrate in the screen. Clayey gravel causes bucket-line, screen, and table troubles. The quantity of gravel bears on amortization costs and determines the economic size of dredge. Seven to 10 yr. is the average life of a wood hull. Capacities of boats are given in Table 43. Shallow deposits (less than 30 ft.) leave ponds too shallow for a large dredge. For tight ground smaller stronger buckets are better; boulders are handled more easily in large buckets. Gravels with large amounts of sticky clay may increase lost time to 50%. Generally with deep noncemented gravel, a large dredge has the lowest operating cost. *Janin* estimates 4 to 5¢ per cyd. for a 15-cu. ft. boat in average gravel 30 to 35 ft. deep, 5 to 7¢ for a 7-cu. ft. boat, and 5 1/2 to 8 1/2¢ for a 5-cu. ft. boat.

3. Bedrock: character and contour. See under 1.

4. Water level and available water. See ***Water consumption***, p. 92.

5. Costs and availability of labor, power, transportation, and supplies. Digging-line and clean-up labor are highly skilled. Power requirements are relatively high and subject to sudden, large fluctuations. Machinery is heavy and special. Adequate machine shops can rarely be maintained except in connection with a dredge fleet operating in one district. Modern steel construction permits sectionalization to an extent that permits hulls of substantially any size, and makes assembly a matter of days. It also makes moving much simpler.

6. Surface contour and timber growth.

7. Operating costs as affected by the above factors.

8. Equipment costs as affected by the above factors, and amortization based on estimated life. Salvage values are low to nil in isolated fields. (Air transport is now practical, although expensive. Dredges weighing 1,200 tons have been flown in.)

9. Costs of land, royalties, insurance, etc.

10. Climatic conditions. Severe winters add materially to operating costs and may, by enforcing shutdowns, add also to overhead. Scarcity of water, and, to a degree, torrential storms have the same results.

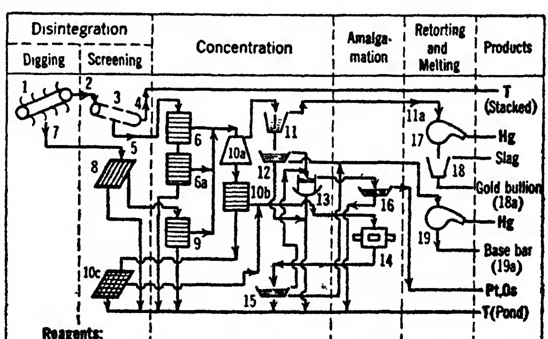
11. Political conditions. Debris laws and resoiling restrictions may almost be depended upon to spring up and harass any successful operation, even though not initially on the statute books. Governments have rediscovered the art of enforcing sales of gold for depreciated currencies. Guards against pilferage may be expected, at any time, to transgress national labor legislation, or, at least, local labor rules. Taxes on gold in place, on the basis of sampling estimates, or on the whim of the local assessor, are not unknown. These hazards are not all, of course, limited to placering.

Lancha Plana Gold Dredging Co. Fig. 47 (*IC 6659*).

Location: 12 mi. west of San Andreas, Calif.

Ore: About 40% gravel and boulders, 40% sand, 20% clay, and about 1 ft. of soft altered porphyry bedrock. Easy digging. Gold comparatively coarse, occurs in both gravel and bedrock; about 1% of total recovery is Pt-group metals.

[General data continued on p. 96.]



Legend for Fig. 47:

1. Bucket line, 6-cu. ft. buckets. High-pressure spray washes out buckets just beyond dump point.

2. Main hopper, 15-cyd. capacity.

3. Revolving screen, 6×33-ft., 1 3/8 in. per ft. slope, 3/4-in. manganese-steel plate, apertures range from 7/16-in. at head to 1-in. at lower end; roller-mounted, 9 r.p.m., drive on lower-end rollers, 30-hp. motor; 18 nozzles on the wash-water pipe; 2 retarding rings.

4. Stacker. 30-in.×92-ft. belt conveyor discharging about 28 ft. above pond level. 7-ply belt with 3/32-in. bottom cover and 1/4-in. (at center) to 1/8-in. (at edge) top cover. Two swinging stops above belt at 30-ft. centers to prevent roll-back of boulders. 22-hp. variable speed motor at outer end of boom.

5. Distributor, steel, 9 openings each side with sliding gates.

6. 9 sluices, 30 in. wide×8 in. deep each side. Slope, 1 3/8 in. per ft. Hungarian riffles 1 1/4(wide) ×1-in., wood covered with 1/8-in. iron, spaced 1 in., 2,000 sq. ft. riffled area in (6) and (9). Quicksilver added at head once daily. Clean-up

FIG. 47. LANCHA PLANA GOLD DREDGING CO.

Legend for Fig. 47—Continued:

at approximately 10-day intervals by standard method (see Sec. 11, Art. 26). About 70% of final concentrate of these sluices is black sand. About 80% of the gold recovered is found in the first 3 ft. of the first three sluices (those taking feed directly from the head end of the screen).

6a. 2 tailing sluices, extending 30 ft. behind boat; 200 sq. ft. riffled area.

7. Spill from bucket line.

8. Grizzly, 2-in. spacing.

9. Save-all sluice, small riffled area; makes about 10% of total gold recovery.

10. Long-tom; *a* = upper unriffled box, *b* = lower box with riffles, *c* = screen at end of *b*. Hand fed. Most of the mercury and gold amalgam and some of the Pt-group metals are caught in (10*a*); the balance of the Pt and some rusty gold and small particles of Hg and amalgam are caught in (10*b*).

11. Bucket containing clean-up of (10*a*); gold amalgam sinks, base amalgam floats and is skimmed off.

11a. Squeezed free of soft mercury. Hard amalgam contains about 55% total Au + Ag.

12. Hand panning.

13. Rocker. Concentrate is about half black sand and half Pt metals by volume.

14. 2 1/2×4-ft. amalgamating barrel. Mercury added and charge ground 1 to 2 hr.

15. Hand panning.

16. H_2SO_4 and zinc shavings cause Pt to amalgamate, after which amalgam is panned away from black sand, washed, excess mercury drained away, and mercury in amalgam dissolved by nitric acid.

17. Retort.

18. Crucible.

18a. Bullion averages 890 parts Au, 20 parts Ag, 20 parts impurity.

19. Retort.

19a. Base bar comprises lead from shot and bullets, and scrap Cu and brass together with $1 to $8 ($35 gold) precious metals per troy oz.

Capacity: 80 to 200 cyd. per hr.; average handled per operating hour (1930), 123 cyd.

Water: 3,500 g.p.m. in circulation; 2,000 g.p.m new water required to maintain pond level; comes 1/2 mi. by ditch after a 45-ft. lift by pump (10-in. centri ugal) from Mokelumne River.

Power: Purchased at aver. price of 1.1¢ per kw-hr. 440-volt motors. 1.88 kw-hr. per cyd., including new water and digging.

Labor: 167 cyd. per man-shift, total.

Running time: 68.3% over year 1930.

Costs for entire dredge operation (1930), 731,637 cyd. (bank measure) excavated: Labor, $0.034 per cyd.; power, 0.020; supplies, 0.042; supervision, office expense, road building, taxes and insurance, depreciation and amortization, 0.051; total, $0.147.

KAMERI GOLD DREDGING Co. dredge on the west coast of New Zealand (*31 CEMR 323*) has 18-cu. ft. buckets, digs from 85 ft. below pond level up to a 35-ft. bank, and stacks up to 65 ft. above pond level with a 220-ft. boom. The gold-saving plant comprises in order: hopper; 8×54-ft. screen with manganese-steel retarder rings and high-carbon steel lifter plates, driven by 100-hp. motor; transverse tables; 6 @ 42×42-in. Bendelari jigs each side; tailing sluice each side. Primary-jig concentrate is elevated to 2 @ 42×42-in. secondary Bendelari jigs in series which make final tailing, clean concentrate from the first hutch, and circulating middling from the remaining hutches. Jig concentrate is barrel-amalgamated. Spill passes over a grizzly, undersize of which is pumped to the screen.

Doodlebugs are gold-gravel concentrating plants of the general dredge type, divorced from the digging mechanism. They may be mounted on a floating hull, or on skids or crawler treads. They are used for small and comparatively shallow deposits (6 to 20 ft. is the best depth range) not large enough for a standard dredge. They are served by an excavator with a considerable range of transport capacity from a given position and with independent mobility, such as a dragline or bucket mounted on caterpillar treads. They have been built up to 7,000 cyd. per day capacity.

Holmes (*21 #11 MJA 13*) recommends a screen of 4 × (at least) 16 ft. with 3/8- to 7/16-in. round-hole plate set at 1 3/4- to 2 1/2-in. slope, for 2,000 to 2,500 cyd. per day of average gravel. An 8-in. centrifugal pump with 60- to 75-ft. lift, with a 3-in. pump for miscellaneous water, will give enough water for this daily capacity; for 3,000 to 4,000 cyd. per day a 10-in. pump is necessary. The water required for disintegration and efficient washing on the screen is normally sufficient for table operation. The hopper should be of generous size, 10 to 12 ft. square, to permit quick spotting; it should be strong and strongly supported to withstand the impact of the dropped load; and the bottom should slope sufficiently to give clean discharge without undue work with the giant. A grizzly over the hopper is usual in bouldery ground; it must be designed to hold back the oversize until it is thoroughly washed. The hopper should be placed high enough to give sufficient headroom for efficient slopes of the screen and tables plus enough drop for efficient distribution. Holmes describes a method, patented by himself, for distribution, which puts all screen undersize through a primary sluice, running forward, on a 1 1/2-in. slope, and subdivides at the end to secondary tables of two to three times the width of the primary on the same grade. Jigs weigh less and require less floor space than tables and hence are desirable for land rigs. Stacker should be 24-in. belt at 300 f.p.m. for a boat with 4-ft. screen; 30-in. for a 5-ft. screen. Shallow diamond ribbing on the carrying surface of the belt gives best service and wear.

First cost of a dragline doodlebug outfit is relatively low; it has the disadvantages that the digging depth is limited, and that the intermittent feeding causes surges in the screen and concentrators.

The PANOB GOLD DREDGING Co., Loomis, Calif. (*22 #14 MJA 4*), has a dry-land plant, built of structural steel, mounted on wide-tread tracklayer-tractor running gear at one end and on wide wheels at the other. It weighs 27 tons and is hauled from place to place by a tractor. It is fed by a 1 1/4-cyd. dragline shovel. It handles 100 cyd. of gravel per hr. and requires 400 g.p.m. of water, at 50-lb. pressure. Screen is 54-in.×20-ft. (6 ft. blank), with 1/4-in. screen. Undersize goes to 4 @ 36-in. rubber-riffled Ainlay centrifugal bowls. Stacker belt is 24-in.×50-ft. Fine tailing is pumped by Hydroseal pump to ponds far enough from the excavation so as not to interfere with bedrock clean-up. The rig is much more stable than a small floating hull, which is important for jig and centrifugal-bowl operation. The apparatus is narrow enough to be moved along highways and other roads of customary width.

LINCOLN GOLD DREDGING Co., Klamath River, near Happy Camp, Calif. (*141 #9 J 57*), operated 1 @ 4,000-cyd. and 1 @ 3,000-cyd. boat, the former with a 2-cyd. and the latter with a 1 1/4-cyd. dragline in ground of 20-ft. average depth for the season Mar. 15 to Sept. 3, 1939, handling 485,910 cyd. of gravel. Costs were \$0.057 per cyd. for the larger boat (which was charged with some inefficient stripping) and \$0.022 for the smaller boat, both costs including moving and washing gravel, but with no charges for royalties or exploration.

At another plant treating 2,050 cyd. per day, with a dragline, cost was 15¢ per cyd.; total equipment cost was \$74,500 (*142 #2 J 76*).

In general the doddlebugs have had a bad economic record over the past 10 yr., largely due, however, to the fact that inexperienced operators have started in on inadequately tested ground, or have built plants too light to stand the punishment of high-tonnage gravel handling. In the hands of experienced operators the doddlebug solves the difficult problem of small-scale relatively cheap treatment of small and shallow deposits. The hull plants have, in general, proved more satisfactory than the land plants, but are not of course, so universally applicable.

Logan (*22 #10 MCJ 56*) reports operating costs for separate-mining boat-type operations ranging from 4 1/4 to 25¢ per cyd.; the low cost was for extremely loose gravel in ground 8 to 12 ft. deep where 225 cyd. (in place) per hr. could be dug, and operating time averaged 18 hr. out of 24; the high figure was with inexperienced operators working a crooked pay streak hard to follow; in average ground the cost should range from 8 to 10¢.

Small portable placer gold-saving units are built by various manufacturers of milling machinery. One form comprising essentially a mechanical rocker, an amalgam trap, and a flotation machine in series consists of a feed hopper with inclined grizzly bottom, mounted on a fixed frame, which wastes oversize and feeds undersize to an inclined screen (about 1/8-in. aperture) mounted in such a way on the frame of a sluice vibrated by an unbalanced pulley that oversize is wasted at the head end of the sluice and undersize feeds the sluice. An amalgam trap receives sluice tailing, which then passes by gravity to a flotation cell of subaeration type so built as to accommodate coarse feed. The sluice has angle iron-type Hungarian riffles followed by coco matting. One motor drives the shaking sluice-screen frame and the impeller of the flotation machine. The unit is 8 ft. long × 4 ft. wide × 5 1/2 ft. high overall and weighs about 2,000 lb. It may, therefore, be transported by truck or trailer, and may be disassembled (bolted joints) for mule-back transportation. Cost, without 3-hp. driving unit, is about 25¢ per lb. Capacity is stated to be about 1 cyd. per hr. A 2 cyd.-per-hr. unit with a compound trommel screen (8- to 10-m. outer jacket) replacing the grizzly and sluice-mounted screen, and an amalgamation plate in the upcoming side of the screen hopper, is 10 3/4 ft. long., 6 1/4 ft. wide, and 7 1/3 ft. high overall, weighs 4,400 lb., requires a 5- to 6- hp. driving unit, can be knocked down, and is sold at the same per-pound price. It is questionable, however, whether the small operator will make any greater savings with such an outfit than he can with a simple sluice line and shoveling-in operation. Other more elaborate plants (*133 J 23*) for hourly yardages of 20 to 100 are provided with a belt conveyor feeding gravel as excavated or grizzly undersize to a compound revolving screen, a roughing jig sending hutch to a shaking table, a scavenger sluice treating jig tailing, a stacker boom for coarse tailing, and, if necessary, a pump for sand tailing, all mounted on caterpillar treads with leveling jacks.

22. CONCENTRATION OF LODE-GOLD ORES

Methods have been classified and discussed generally in Art. 19. Typical examples follow.

Gravity concentration + amalgamation

White Swan Gold Mines, Inc. Fig. 48 (*IC 7015, p. 26*).

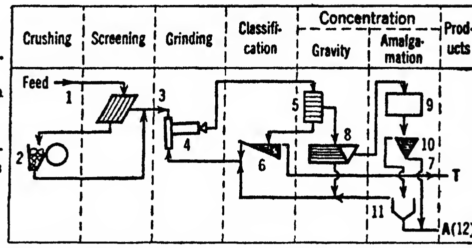
Location: 15 mi. from Baker, Oreg.

Ore: Semi-oxidized pyritic quartz in a shear zone in argillite.

Capacity: 40 tons per 24 hr.

Assays: Feed, \$40 (\$35 gold) per ton; tailing, \$2. Tailing assay remains substantially constant with considerable rise in feed assay.

Recovery: 80% upward, according to feed assay.



Legend for Fig. 48:

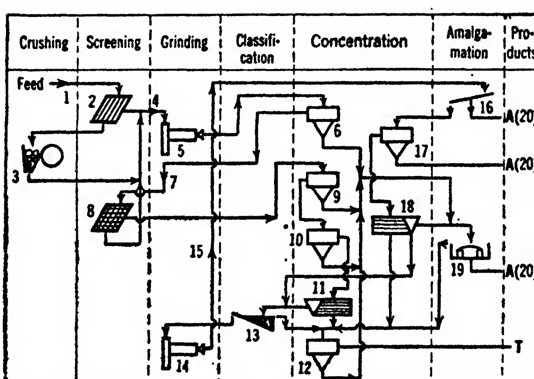
1. 40-ton conical steel bin.
2. 1 @ 9×15-in. jaw crusher, 3/4-in. open setting.
3. 1 @ 16-in. belt conveyor; 1 @ 50-ton cylindrical steel bin.
4. 1 @ 5×4-ft. Marcy ball mill.
5. 1 @ 2×12-ft. blanket table (6 sections, each 2-ft. square); a 2×8-ft. table is in reserve.
6. 1 simplex rake classifier.
7. 80% <100-m.
8. 1 @ No. 12 Wilfley table.
9. Amalgam barrel. Ground 18 hr. with lye, 6 hr. with mercury.
10. Amalgam separator comprising an 8-in. funnel and 1-qt. fruit jar arranged by means of a 2-hole cork to supply rising water through the funnel and collect settled amalgam in the jar.
11. Amalgam trap.
12. To retort, see Sec. 14, Art. 9.

FIG. 48. WHITE SWAN GOLD MINES.

Summary. One-stage crushing and one-stage grinding to about 48-m. Gravity concentration in the grinding circuit, comprising roughing on a blanket table and cleaning on a shaking table. Gravity tailing deslimed at 48-m., slime discarded and sands returned to grinding mill. Gravity concentrate amalgamated.

Talache Mines, Inc. Fig. 49 (*IC 6985*).

Location: Quartzburg, Idaho.
Ore: Metallic gold in quartz veinlets in a crushed rhyolite porphyry; small amounts of pyrite, galena, sphalerite, galenobismuthinite, tetradymite, and tetrahedrite accompany the gold.
Capacity: 100 to 150 tons per 24 hr., 120 average.
Assays: Feed, 0.20 oz. Au per ton; tailing, 0.019 oz.
Recovery: 90%.
Water comes by gravity from a reservoir fed by a mountain stream. CONSUMPTION, 8.3 tons per ton of ore.
Running time: 90%.
Labor, 20 tons per man-shift.



Legend for Fig. 49:

1. 10-in. stope grizzlies; 100-ton bin with apron feeder.
2. Grizzly, 1-in. spacing.
3. 1 @ 20×10-in. jaw crusher, 1 1/2-in. open setting.
4. Bucket elevator, 12×7 1/4-in. buckets, 41-ft. lift, 370 f.p.m.; 145-ton bin; belt-conveyor feeder, 5 f.p.m.
5. 1 @ 8-ft.×22-in. conical ball mill, 18 r.p.m., 65% solids, 4- and 5-in. forged-steel balls (2.25 lb. per ton) and common chilled gray cast-iron liners (local; 0.63 lb. per ton), 150-hp. motor with silent-chain and spur-gear drive.
6. Hydraulic gold trap (see Fig. 50). For somewhat more elaborate form see *60 CMJ* 537.
7. Bucket elevator, 34-ft. lift, 350 f.p.m.
8. Hum-mer V-32 screen, 35-m. Ton-Cap.
9. 3 traps as (6).
10. 4 traps as (6).
11. 4 Wilfley tables.
12. Large trap as (6).
13. Belt-drag classifier.
14. 1 @ 4×3-ft. ball mill, 2-in. forged-steel balls (1.3 lb. per ton), cast-iron liners (0.40 lb. per ton), 30 r.p.m., 70% solids, 25-hp. motor with friction clutch.
15. Wilfley sand pump.
16. 2 @ 4 1/2×8-ft. amalgamation plates, 2 1/16 in. per ft. slope.
17. 2 traps as (6).
18. 2 Wilfley slime tables.
19. 1 @ 24-in. and 1 @ 22-in. amalgamation muller in parallel.
20. Retorted and melted to bullion; slag returned to (13).

FIG. 49. TALACHE MINES.

Cost, per ton (1936): Crushing, \$0.13; grinding, 0.345; amalgamation, 0.062; gravity concentration, 0.048; superintendence, 0.055; total, \$0.640.

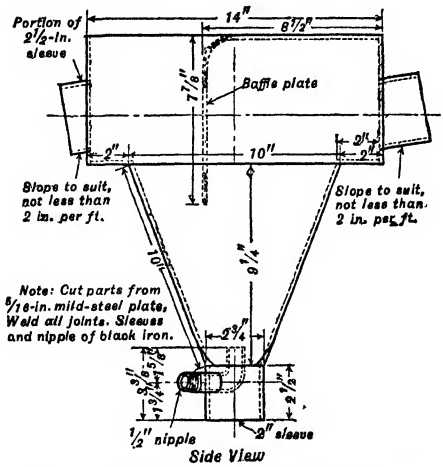


FIG. 50. Hydraulic gold trap, TALACHE MINES.

Summary. One-stage crushing and one-stage primary grinding in closed circuit with a 35-m. screen. Primary concentration by traps and shaking tables; rougher concentrate reground and cleaned by table. Concentrate amalgamated.

Amalgamation ± gravity concentration + cyanidation

The underlying idea of this method of treatment is to use a relatively cheap quick method of separating coarse gold in order to remove the burden of dissolving such gold from the cyanide process. To be amenable a part of the gold must be clean and bright and substantially free from other minerals at relatively coarse sizes.

At certain MOTHER LODE mines, ores containing coarse gold together with carbonaceous slime are treated by gravity concentration in the grinding circuit, the concentrate being amalgamated; the ground product is separated into sand and slime and the sand cyanided by percolation; slime is floated with discard of tailing; and the carbonaceous sulphide concentrate is roasted and cyanided.

When gold is too coarse for a jig (*i.e.*, would not pass into the hutch), some form of riffle or trap precedes the jig, and the same principle is employed when tables are used in the grinding circuit (see IDAHO-MARYLAND, Fig. 64). At ARNTFIELD (*Bul 342 CIMM 407*) a jig is used to scavenge sand tailing after cyanidation from an 85% <200-m. grind; it reduces the grade from 0.0085 oz. Au to 0.0063 oz. and makes a concentrate assaying 0.055 oz., which is fed back to the grinding circuit.

Homestake Mining Co. Fig. 51 (*Q* by A. J. Clark, Chief Metallurgist; Nathaniel Herz, Chief Chemist; *IC 6408; 132 J 298*).

Location: Lead, S. Dak.

Ore, approximate composition: Quartz, 30%; cummingtonite, 30; chlorite, 15; biotite, 10; garnet, 3; iron oxides, 2; carbonates, 2; porphyry, 2; pyrrhotite, 4.5; pyrite, 2; arsenopyrite, 0.5; chalcopyrite, trace. Substantially free of carbonaceous and clayey material.

Capacity: 3,800 tons per 24 hr.

Assays: Feed, 0.4 oz. Au per ton; tailing 0.02 oz.

Recovery: 95%+.

Water from Spearfish and other creeks; 75% re-used; 7 tons gross per ton milled.

Power: Company operates two hydroelectric and one steam plant; CONSUMPTION, 13.8 hp-hr. per ton milled.

Labor: American. Tons per man-shift, total 75.

Running time: 96%; loss due to renewals and adjustments.

Mill building: Sloping site; steel frame, wood and corrugated-iron siding, Barrett roofing, concrete floors; heated.

Distances: 5/8 mi. mine to mill by compressed-air locomotive and 4-ton cars.

Tailing disposal: Sand sluiced into mine; slimes to creek.

Summary. Four-stage crushing to <3/4-in.; 2 closed-circuit grinding stages in series to 65-m. with amalgamation in both circuits; sand and slime cyanidation.

Legend for Fig. 51:

1. Underground. Items 2 to 5 repeated on 800-, 1,400- and 2,200-ft. levels.

2. Grizzly, 12 bars 3 1/2 in. deep×6 ft. long, spaced for 6-in. openings.

3. About 70% of feed; apron feeder.

4. 1 @ 36×48-in. Traylor Bulldog jaw crusher, 3 1/2-in. open setting, 125-hp. motors, capacity 250 t.p.h.

5. Loading pocket; shaft skips.

6. Grizzly, 1 1/2×1×6-in. cast-iron wedge bars set in a cast-iron comb support on I-beams; 3-in. aperture.

7. 2 S-A apron feeders.

8. 4 @ 12-in. A-C gyratory crushers, 3-in. open setting, 25-hp. motors.

9. 1 @ 36-in. belt with magnetic head pulley.

10. Trommel, 3-in. apertures.

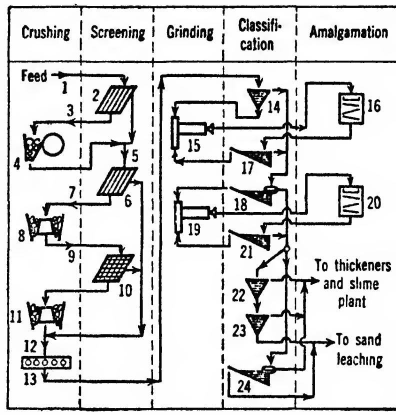
11. 2 @ 12-in. A-C gyratory crushers, 2 1/2-in. open setting, 35-hp. motors.

12. Shuttle conveyor; bin; air-locomotive trains of 30 @ 4-ton cars; 7,200-ton mill bins with suspended-type Challenge feeders.

13. 165 @ 1,594-lb. (when new) stamps, 100 @ 7-in. drops per min.; 1-4-3-2-5 sequence, 5/8- to 1-in. woven-wire screens, life 22 to 30 days according to steel. Capacity, 1 ton per stamp per hr.; power consumed, 16 hp. per 5-stamp battery; 20% solids; 90 stamps per man; about 4% lost time, due principally to renewals. Mortar weighs 7,500 lb.; pocket lined with cast iron, sides with boiler plate, back with manganese steel. Dies, white iron, weigh 165 lb. new and 70 lb. when discarded after 45 days. Shoes, manganese steel, weigh 250 lb. new and 45 lb. when discarded after 135 days.

14. 10 @ 7-ft. 65-deg. dewatering cones.

15. 7 @ 5×10-ft. A-C and 3 @ 6×12-ft. Marcy rod mills; mercury fed into mills.



16. 10 Clark-Todd amalgamators.

17. 7 @ 4 1/2×21 1/3-ft. and 3 @ 6×28 1/3-ft. rake classifiers, 2 3/4-in. slope, 24 1/2 and 31.5 s.p.m. respectively.

18. 4 @ 12(diam.)×6×26 2/3-ft. bowl-rake classifiers, 1 1/8 r.p.m. and 13 1/2 s.p.m.; and 1 @ 16(diam.)×6×31 2/3-ft. bowl-rake classifier, 2 r.p.m. and 20 s.p.m.

19. 6 @ 5×14-ft. Marcy ball mills.

20. 6 as (16).

21. 4 @ 6×26 2/3-ft. and 2 @ 6×23 1/3-ft. rake classifiers, 2 3/4- and 2 1/2-in. slopes, and 20 and 18 s.p.m. respectively.

22. 8 @ 10-ft. 50-deg. cones.

23. 10 @ 8-ft. 50-deg. cones.

24. 2 @ 20(diam.)×6×33 1/3-ft. bowl-rake classifiers, 0.6 r.p.m. and 8 s.p.m. (Reeves drive.)

Fig. 51. Homestake Mining Co.

Dome Mines, Ltd. Fig. 52 (*Q* by J. J. Davis, Mill Sup't, V. H. Humphries, Metallurgist).

Location: South Porcupine, Ont., Canada.

Ore: 30 to 45% quartz, 30 to 40% silicates (greenstone), 3 to 4% pyrite, 0.3 to 1% pyrrhotite, 10 to 15% ankerite; no carbonaceous or clayey material.

Capacity: 1,650 tons per 24 hr.

Assays: Feed, 0.335 oz. Au per ton; tailing, 0.008 oz.

Recovery: 97.6%.

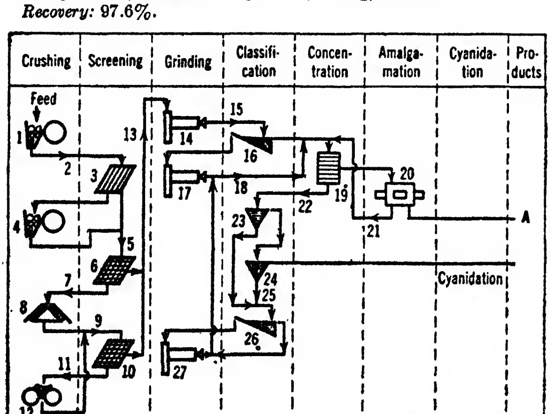


Fig. 52. Dome Mines.

Legend for Fig. 52:

1. 1 @ 36×54-in. Buchanan jaw crusher.

2. 1 @ 560-ton bin; 1 @ 20-ton car; 1 @ 80-ton surge bin.

3. 1 rotary-disk grizzly feeder; 16 @ 24(diam.)×1/2-in. plates spaced 3 1/2-in. centers.

4. 1 @ 24×36-in. Farrell B jaw crusher, 4-in. open setting (1 @ No. 7 1/2 gyratory as stand-by).

5. 1 @ 24-in. belt conveyor with 1 @ 30-in. suspended magnet.

6. 1 @ 8×4-ft. 2-vibrator Hum-mer screen, 1×3/4-in. aperture.

7. 1 @ 24-in. belt conveyor.

Water: Pumped 3 mi. from Porcupine Lake; 120 hp. required. Net CONSUMPTION, 1 ton per ton of ore milled.

Power: Purchased; comes 2 mi. at 12,000 volts; motors, 550-volt, 25-cycle; CONSUMPTION, 35.3 hp-hr. per ton.

Labor: Canadian. Tons per man-shift: operating, 38.4; repairs, 118.

Running time: 98.3%. Losses due to ball mills and power off.

Mill building: Sloping site. Frame, concrete and wood floors. Office and amalgamation room only heated. Machinery handling by chain blocks throughout.

Distances: 950 ft. mine to mill by 25-ton car on tail-rope haul. Standard-gage railroad on property.

Tailing disposal: 10-in. wood-stave pipe 4,000 ft. by gravity to tailing dam.

Summary. Four-stage crushing to <3/8-in., the last stage in closed circuit with a screen. Three-stage grinding, the first stage open-circuit. Blanket tables supplemented by amalgamation remove coarse gold from the second-stage grinding circuit. Blanket-table tailing is cyanided.

Yellow Aster mill (Anglo American Mining Corp.). Fig. 53 (*140 # 10 J 32, IC 7096*).

Location: Randsburg, Kern County, Calif.

Ore: Gold in quartz and monzonite; oxidized and free-milling.

Capacity: 3,000 tons per 24 hr.

Assays: Feed: \$0.85 to \$1.00.

Power: Purchased at 33,000 volts; motors, 150-hp. and larger @ 2,400-volt, smaller @ 480-volt.

21. About 20% of total feed.

FIG. 53. YELLOW ASTER mill.

Water: From wells; pumped 7 1/2 mi. against a total head of 2,710 ft.; total input power, 289 hp.
Costs (1938): Crushing, screening, and waste disposal, $0.155 per ton milled; milling including cyanidation $0.140; total $0.295.

Summary. Two-stage crushing from 2 1/2-cyd. shovel material to 1/4-in. in jaw crusher and reduction gyratory; one-stage closed-circuit grinding to 4-m. Two-stage rough concentration at <1/4-in. and <3-m. in jigs, with cleaning of jig hutch on tables and continuous barrel amalgamation of table concentrate. Slime tailing to cyanidation.

Straight Cyanidation

This method is the one used in the majority of large-tonnage gold-ore mills, if not, perhaps that applied to the bulk of gold-ore tonnage. It is the method of the Rand mills, of many of the larger Canadian mills, and of a considerable number of the mills in the United States. The typical flowsheet is 2- or 3-stage crushing, 2- or 3-stage grinding to upward of 80% <200-m., and either sand-slime or all-slime cyanidation. In general all-cyanide plants are medium- to high-tonnage mills for the reason that they are the most expensive both to build and to operate, that their economy is not clearly demonstrable for low-grade ores on a low tonnage basis, while with high-grade ores at a small mine the usual tendency is to gut the mine, and the question of maximum economy is not, ordinarily, closely investigated.

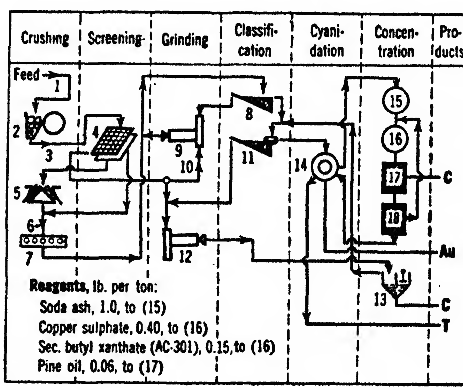
Concentration by gravity, flotation, or amalgamation in the grinding circuit is increasingly the practice in cyanide plants, even when the gold is not so coarse as to require it. It has the advantage of early recovery of values, but the disadvantage that it increases opportunity for theft.

Cyanidation + flotation

This method of treatment is applied to ores which contain appreciable percentages of the total gold dispersed relatively finely in nonsulphide rock, and a further finer portion in sulphides, which may or may not be harmful in cyanidation; in the former case, concentrate made from cyanide tailing is shipped to a smelter; in the latter case concentrate is reground and cyanided, either separately or joined back into the main stream.

Kelowna Exploration Co. Fig. 54 (*Q* by Geo. L. Mill, Mill Sup't).

Location: Hedley, B. C., Canada.
Ore: Arsenopyrite, 5 to 12%; pyrrhotite 4 to 12; chalcopyrite, 0.40; minor amounts of pyrite, sphalerite, cobalt and nickel sulphides in argillite. There are no carbonaceous or clayey materials in the ore that interfere with cyanidation.
Capacity: 250 tons per 24 hr.



Legend for Fig. 54:

FIG. 54. KELOWNA EXPLORATION CO.

Assays: Feed: Au, 0.38 oz. per ton; As, 4.5%; Cu, 0.20%; tailing, 0.025 oz. Au, 0.70% As, 0.03% Cu.; concentrate: Au, 1.00 to 1.15 oz. per ton; As, 26 to 32%; Zn, 1 to 1.5%; Cu, 1.5 to 2.5%; insol., 8%.
Recovery: 70% by cyanidation; 24% by flotation.
Ratio of concentration: 15 : 1.
Water comes 3 mi. by gravity through wood-stave pipe from mountain stream; CONSUMPTION, 7.5 tons per ton milled, none re-used.
Power purchased; comes 200 mi. at 66,000 volts; motors, 2,300- and 440-volt, 60-cycle.
Labor: Canadian. Tons per man-shift: operating, 20; repairs, 65.
Running time: 99.2%.
Mill building: Sloping site. Wood frame, covered with corrugated iron. Floors wood in grinding plant, concrete in cyanide and flotation sections; level, benched. Heated with unit heaters. Trolleys and chain blocks for handling machinery.
Distances: 3 mi. mine to mill; 1 1/2 mi. by locomotive, 1 1/2 mi. by gravity surface tram. Nearest railroad, 1/4 mi. Concentrate shipped 400 mi. with 9.5% moisture.
Tailing impounded; clear water overflows a central weir.

Summary. Three-stage crushing and 2-stage closed-circuit grinding in water, jig in second stage, to 98.5% <200-m.; cyanidation, flotation of cyanide tailing, and retreatment of flotation tailing by cyanide.

Wright-Hargreaves Mines, Ltd. Fig. 55 (M. Black, Mill Sup't, *140 #3 J 29; 140 #4 J 37; 140 #5 J 42*).
Location: Kirkland Lake, Ont., Canada.
Ore: Tellurides and small amounts of sulphide in hard andesite porphyry. Complete analysis: Au, 0.66 oz. per ton; Ag, 0.10 oz.; Fe, 2.6%; Pb, 0.014%; Cu, 0.008%; Te, trace; S, 0.7%; MoS_2, trace; SiO_2, 66.2%; Al_2O_3, 13.3%; CaO, 3.6%; MgO, 1.7%; Na_2O, K_2O, 7.1%; CO_2, 3.1%.
Capacity: 1,200 t.p.d.
Assays: Feed, $21.75 per ton; tailing, $0.72 per ton.
Extraction: 96.5%.
Power: Purchased; comes in at 2,200 volts; 550-volt motors; CONSUMPTION, 52.8 hp-hr. per ton milled.
Mill building: Steel and concrete. Walls of 1 3/4×12-in. Douglas-fir shiplap, 1/2-in. Celotex, and rigid asbestos shingles; roof of 2 3/4×12-in. shiplap, 1/2-in. Celotex, 1 3/4×12-in. shiplap, 1/2-in. Celotex, and Twenty-year built-up roofing. Both layers of Celotex were laid in asphalt. This elaborate construction is to insure against inside sweating. Heating is by steam unit heaters.
Tailing disposal: Tailing is pumped into a 30-in.×89-ft. steel standpipe, thence by 12-in. wood-stave pipe 2 mi. to a disposal site. Standpipe is fed at 46 ft. above the ground (slightly above normal pulp level) from a 5×5-in. rubber-lined centrifugal pump with 35-hp. motor. Velocity in pipe line is 1.6 f.p.s.
Distances: Mill at mine shaft.
Costs: (1937) Crushing, $0.105; primary grinding, 0.231; secondary grinding, 0.221; filtering, 0.104; thickening, 0.066; agitation, 0.038; precipitation, 0.033; sampling and assaying, 0.043; refining, 0.016; lighting, 0.011; heating, 0.011; flotation, 0.104; tailing disposal, 0.035; reagents, 0.104; superintendence, 0.025; miscellaneous, 0.015; total, $1.16.

32. 1 @ 5 ft.×22-in. Hardinge ball mill, 3~4-in. lumps of ore used as grinding media. 25 lb. dry lime per ton of solid added to mill.

33. 1 @ 2-in. A-C pump. Strong cyanide added here. 70% of gold dissolved in a few minutes but for remaining extraction up to 97% requires 2 to 3 weeks' agitation.

34. 7 @ 12×12-ft. Denver-Wallace agitators in series.

35. 2 Wilfley pumps.

36. 1 @ 34.5×9-ft. thickener.

37. 1 @ 4-in. diaphragm pump.

38. Discarded because of inability to control frothing, if re-used, and to the further fact that its use produces high tailing and low-grade concentrate.

Summary. Three-stage crushing in jaw crusher and cones from 10-in. to <1/4-in.; feeds to the cones are scalped and the crushing circuit is closed by a final screen. Two-stage grinding in ball and tube mills, each stage in closed circuit. Cyanidation by agitation and filtration, with intermediate flotation, regrind of concentrate, and concentrate leaching in a separate slime circuit with prolonged agitation prior to return of the pulp to the main circuit.

Flotation was introduced to reduce mill space required for prolonged agitation due to telluride gold. The point of introduction of the operation was that at which the cyanide extraction-time curve began to flatten, *i.e.*, where easily dissolved gold had been removed.

Flotation + cyanidation of concentrate

This method is practiced on ores in which the gold is markedly concentrated in the sulphides in which these minerals free at a size much coarser than that at which the gold is freed, and are either not refractory to cyanidation or can be rendered amenable to cyanidation by roasting, leaching, or other treatment. It has the advantage that much finer grinding of gold-bearing particles (*e.g., 40% <10-μ*) is thus economical than would otherwise be the case; the disadvantage is that cyanide-refractory materials may become concentrated in cyanide-plant feed to such an extent as to interfere seriously. Use of the combination process is increasing, particularly in small mills.

McIntyre Porcupine Mines, Ltd. Fig. 56 (*Q* by J. J. Denny; *134 J 472*).

Location: Schumacher, Ont., Canada.

Ore: Quartz, porphyry, and schistose basalt and dacite; pyrite content averages 7 to 8%. Gold is predominantly in the pyrite.

Capacity: 2,400 tons per 24 hr.

Assays: Feed: Au, 0.279 oz. per ton; flotation tailing, 0.013 oz.; total tailing, 0.015 oz.

Recovery: 94.6%.

Water pumped 300 yd. from lake; power consumption, 84 hp.; total water CONSUMPTION, 2 1/4 tons per ton of ore, none re-used.

Power: Hydroelectric, purchased. Comes 7 to 164 mi. at 12,000 to 110,000 volts; motors, 2,200- and 440-volt, 25-cycle. CONSUMPTION, 20.7 hp-hr. per ton milled.

Labor: Canadian. Tons per man-shift: crushing, 200; milling, 73; repairs, 200.

Running time: 98.7%. Lost time due to power interruptions and to tube-mill and classifier repairs.

Mill building: Level site. Steel frame, 8-in. hollow-tile walls, concrete floors sloping 1/8 to 1/2 in. per ft. Crushing plant heated; mill proper not. Power cranes in crushing, grinding, and flotation bays.

Distances: Mill at mine. Railroad runs through plant yard.

Tailing disposal: A settling pond was built by raising a dam with a mechanical shovel. Sand tailing s deposited on the original dam by pipe line and sand spigots; slime is diverted into pond. The sand s worked up by mechanical shovel as necessary.

Costs (1933): Crushing and conveying, $0.107; flotation, 0.363; cyanidation, 0.273; refining, 0.022; assaying, 0.015; mill alterations, 0.004; total, $0.785.

16. As (14); concentrate, 0.25 oz. Au, tailing, 0.013 oz.

17. 400 tons per 24 hr. assaying 65% pyrite and 3.2 oz. Au per ton.

FIG. 56. McINTYRE PORCUPINE crushing, grinding, and flotation mill.

Summary. Three-stage crushing and one-stage closed-circuit grinding to 10% >65-m. flotation feed. Unit-cell and one-stage rougher flotation making a 6 : 1 ratio of concentration; concentrate reground to 80% <325-m. and cyanided.

Wiluna Gold Mines, Ltd. Fig. 57 (*Q* by Metallurgical Staff; *43 MM 58*).

Location: Wiluna, Western Australia.

Ore: Gold-bearing pyrite and arsenopyrite in quartz, calcite, siderite, and chlorite.

Capacity: 1,550 tons Wiluna ore as above; 350 tons Moonlight ore, containing additionally stibnite.

Assays: Feed, 0.225 oz. Au per ton; concentrate, 2.25 oz.; tailing (flotation + cyanide), 0.043 oz.

Recovery: Flotation, 90%; cyanidation of calcined flotation concentrate, 90% on concentrate; overall, 81%.

Ratio of concentration: 10 : 1.

Water from wells pumped 3 mi.; 45 hp.; CONSUMPTION, 1 ton per ton of ore, net; 70% re-used. Prior to 1935 salt water (12% salt) was used; change to fresh water resulted in better recovery in flotation and quicker settling in thickeners.

Power: Diesel generated; motors, 440- and 3,300-volt, 50-cycle; CONSUMPTION, 50 hp-hr. per ton milled.

Labor: English-speaking.

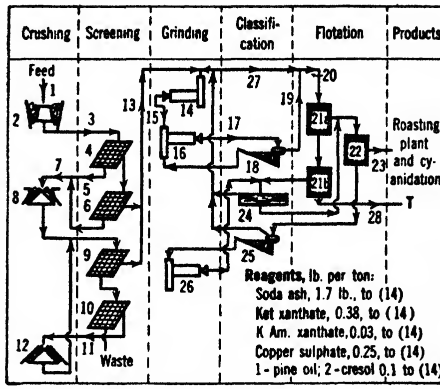
Running time: 97.5%. Principal loss due to mill repairs.

Mill building: Level site. Steel, concrete floors. Unheated. Machinery handled by 5-ton crane and chain blocks.

Transport: Conveyor belts 2,200 ft. mine to mill; railroad siding at property.

Tailing disposal. See flowsheet item 28.

Costs (milling only): Crushing, 6.7¢ per short ton; conveying, 2.5¢; ball milling, 14.5¢; tube milling, 20.6¢; classification, 1.7¢; thickening, 1.4¢; flotation machines, 7.4¢; flotation reagents, 17.1¢; pumping and filtering, 5.7¢; tailing disposal, 1.6¢; total, 79.2¢.



Legend for Fig. 57:

1. R.o.m. < 12-in.; 56-ton coarse-ore pocket; Ross chain feeder (6 @ 2 1/2-in.× 28 1/2-ft. chains, 13 1/2-in. links, 3 speeds, 7 1/2 f.p.m. usual speed).

2. 1 @ 20-in. gyratory crusher, 3-in. open setting. Capacity, 250 t.p.h.; normal rate, 150 t.p.h.

3. 1 @ 24-in.×250-ft. belt conveyor; 1 @ 36-in. pan magnet suspended over head pulley.

4. Finger grizzly, S-bars 1 1/2×7-in. spaced 2 in., finger speed 17 r.p.m.

5. Inclined chute with 6-chain Ross feeder, 2 r.p.m.; 1 @ 48-in. belt conveyor with bipolar suspended magnet. Coarse (6∼4-in. ring) lump ore picked here for tube-mill pebbles.

6. Hum-mer screen, 1/2-in. aperture.

7. 2 surge bins each with 1 @ 5-chain Ross feeder (2-in. chain, 3 speeds, 3 r.p.m. normal).

8. 2 @ 4-ft. standard cone crushers, set 3/8-in.

9. 2 @ 4×6-ft. Hum-mer screens, 7/16-in. aperture, manganese-steel cloth gives 55,000-ton life.

10. Small trommel with 2 1/4-in. sq. aperture to remove chips.

11. Surge bin with 24-in. belt feeder.

12. 1 @ 4-ft. short-head cone set 3/16-in.

13. 2 @ 24-in. belt conveyors in series transport 1,050 ft.; Blake-Denison weightometer; tripper to 4 @ 32 (diam.)×25-ft. cylindrical steel ore bins; 3 gravity-type Burma feeders per bin feed to 1 @ 16-in. variable-speed belt conveyor with automatic siren alarm for feed stoppage. Each bin feeds one of four separate units, items 14 to 20.

14. 1 @ 8-ft.×36-in. conical ball mill. 30× 30-in. trunnion trommels, 5/16-in. aperture.

15. 2-in. Wilfley pump.

16. 2 @ 5 1/2×22-ft. tube mills with 3/8-in. trunnion trommels which remove coarse grinding medium; this is discharged onto a belt conveyor which discharges to a 25-ton bin whence it is trammed back to the crushing plant.

17. 1 @ 4-in. Wilfley pump.

18. 1 @ 15 1/2 (diam.)×8-ft. bowl-rake classifier; overflow, 28% solids, 30% > 200-m.

19. 1 @ 30 (diam.)×10-ft. conditioner, 8 r.p.m., 15-hp. motor, 40-min. time-factor; pH on exit about 8.6.

20. 1 @ 6-way distributor.

21. See note (13). 4 @ 10-cell and 1 @ 8-cell 24-in. M-S subaeration machines and 1 @ 10-cell 56-in. round-overflow Fagergren machine in parallel; a = first 4 cells; b = remainder. Subaeration machines take air at 4 lb. pressure, consume about 50 hp. for air for 56 cells; shrouded impellers have 4-in. at 45° blades, local cast iron, life 9 to 10 mo. Fagergren cells, 575 r.p.m.; local cast-iron rotors, 2 3/8-in. bars, last 5 mo., rubber-covered 9 to 10 mo., local cast-iron stator, 5 1/2 mo.

22. 2 @ 4-cell 24-in. M-S subaeration machines in parallel.

23. 1 @ 60×10-ft. thickener; 1 @ 20 (diam.)× 10-ft. Goldfield agitator, 10 r.p.m.; 2 @ 12 (diam.) ×11 1/2-ft. Oliver filters.

24. 1 @ 18-ft. (diam.) classifying thickener, 1.5 r.p.m.; overflow, 12% solids, split as indicated; underflow, 45% solids.

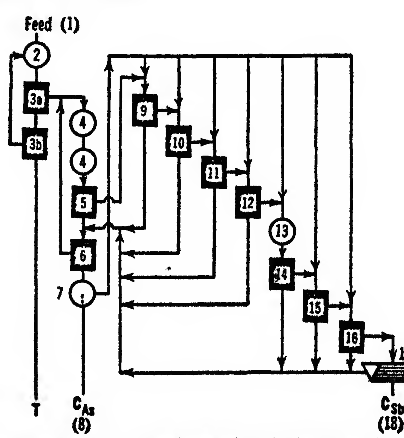
25. 1 bowl-rake classifier, as (18).

26. 1 tube mill, as (16).

27. To cell No. 3 of Fagergren machine.

28. 1 @ 6-in. Wilfley pump (1 reserve); 2 @ 100-ft. and 2 @ 120-ft. thickeners in parallel, 27% solids in feed, 53% (aver.) solids in underflow, clear overflow represents 68% recovery; 2 @ 6-in. Wilfley pumps 1,950 ft. to tailing dam.

FIG. 57. WILUNA GOLD MINES.



Legend for Fig. 58:

1. Substantially 65-m. 2.0 lb. per ton of soda ash, 0.4 lb. KEt xanthate, 0.1 lb. KAm xanthate, 0.7 lb. lead nitrate and 0.1 lb. of 1-pine oil : 2-cresol added at primary ball mill (item 14, Fig. 57).

2. Surge tank.

3. 1 @ 56-in. (rd.) 10-cell Fagergren machine; a = cells 1, 2; b = cells 3 to 10.

4. 2 vortex conditioners in series; 1 lb. per ton sodium hydroxide and 3 lb. sodium cyanide added at first conditioner.

5. 1 @ 24-in. M-S cell.

6. 1 @ 24-in. 2-cell M-S machine.

7. 1 @ 25-ft. thickener.

8. Underflow of thickener is auriferous concentrate which is dewatered (solution is precipitated) and joins Wiluna concentrate (Fig. 57).

9. 1 as (5).

10, 11, 12. 1 Forrester cell.

13. Conditioning tank.

14, 15, 16. 1 Forrester cell.

17. 1 shaking table.

18. Stibnite concentrate dewatered, washed, and shipped; solution precipitated with that from (8).

FIG. 58. Flotation routing for Moonlight (WILUNA) stibnite ore.

Summary. Three-stage crushing; 2-stage grinding (first stage open-circuit) to 65 *mog.* Flotation by rougher-cleaner routing with regrind of cleaner tailing. Concentrate calcined and cyanided.

Ore from the Moonlight mine, containing substantially nonauriferous stibnite and auriferous arsenopyrite is crushed and ground to flotation size in a flowsheet substantially like Fig. 57, then floated as in Fig. 58.

Buena Vista Mining Co. Big Missouri mill. Fig. 59 (*Tref, 11/40; Bul 31[2] CIMM 329*).
Location: Joker Flats, B. C.
Ore: Native gold with pyrite, galena and sphalerite in volcanic tuff.

Legend for Fig. 59:

1. 16-in. stope grizzlies; 4-ton cars; 1,400-ton coarse-ore bin with 4-ft. compressed-air undercut arc gate. Feed chute is covered with a chain curtain, 1 1/4-in. stock, with 60-lb. rail attached for extra weight.
2. 1 @ 30×42-in. Traylor jaw crusher, 2 1/2-in. open setting, 150 r.p.m.
3. 1 @ 30-in. conveyor; 2 magnets.
4. 1 @ 5×10-ft. Ty-rock screen, 7/8-in. aperture.
5. 1 @ 3-ft. Traylor TY reduction gyratory, 3/4-in. set.
6. Bucket elevator.
7. 1 @ 24-in. conveyor with tripper; single-bucket sampler; 3 @ 350-ton bins; 3 Hardinge constant-weight feeders with revolution counters, automatic signals, and no-load cutoff controls; 3 @ 24-in. belt conveyors.
8. 3 @ 6×12-ft. Cole-Bergman ball mills; 23.9 r.p.m.; 150-hp. motors with magnetic clutches and speed reducers; discharge, 70% solids; manganese-steel liners, 0.4 lb. per ton; 3- and 4-in. balls, 2.4 lb. per ton.
9. 3 @ 16×24-in. Denver duplex jigs. 227 @ 1/4- to 5/16-in. s.p.m.; 3/16-in. steel shot for bedding, 2-mm. screen.
9a. By-pass.
10. 3 @ 8×24-ft. duplex rake classifiers; overflow, 28% solids, 65% <200-m.
11. 1 @ 10-cell 24-in. M-S subaeration machine; 50-hp. motor with V-belt drive.
12. To 1 @ 6×6-ft. ball mill in closed circuit with 3×25-ft. rake classifier and cyanidation.
13. Thickened, filtered, repulped, reground, and cyanided.

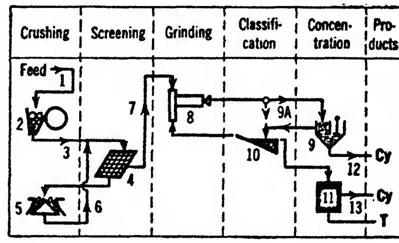


FIG. 59. BUENA VISTA MINING CO.

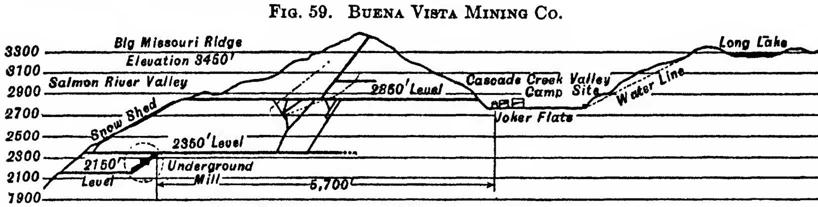

FIG. 60. Transverse section of BIG MISSOURI (BUENA VISTA) mine and mill.

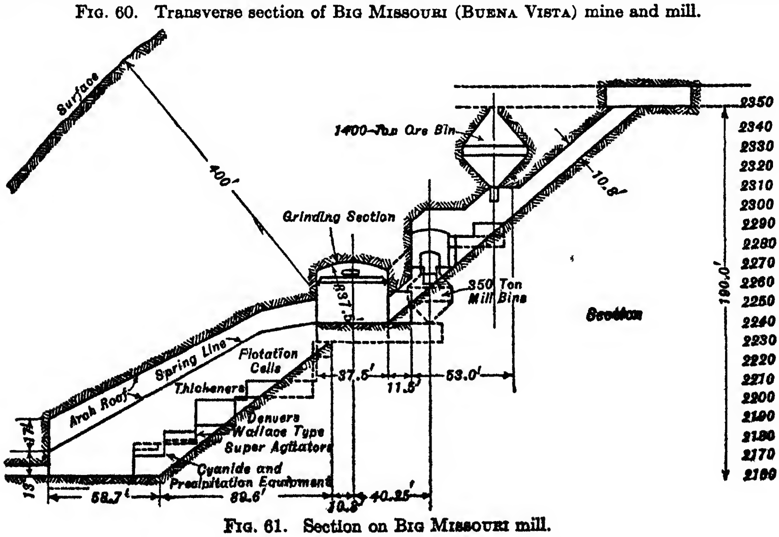

FIG. 61. Section on BIG MISSOURI mill.

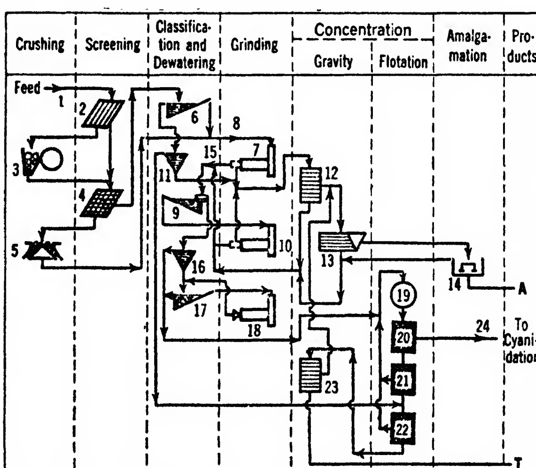
Capacity: 750 tons per 24 hr.
Recovery: Flotation and jigging, 95%; cyanidation, 95%.
Ratio of concentration: 16 : 1.
Water: Comes from drainage ditch on 2,350-ft. level (see Fig. 60).
Power: Company-generated.
Mill building: Underground (see Figs. 60 and 61). Unheated. Country is steeply mountainous Sixty feet of snowfall between Oct. and Apr.

Summary. Two-stage crushing, 1-stage grinding to 65-m., gravity concentration and flotation with rejection of about 95% of feed. Regrind and cyanidation of gravity and flotation concentrate.

Suyoc Consolidated Mining Co. Fig. 62 (*Q* by John N. Butler, Ass't Mill Sup't; *138 J 415*).

Location: Near Baguio, Mountain Province, Philippine Islands.
Ore: Chalcopyrite, 0.32%; pyrite, 8.15%, sphalerite, 0.29%; galena, 0.97%; calcite, 5.35%; insol., 85.5%.
Capacity: 220 tons per 24 hr.
Assays: Feed: Au, 0.343 oz. per ton; Cu, 0.15%; Fe, 3.9%; Zn, 0.2%; Pb, 0.84%; CaO, 3.0%; insol., 85.5%; concentrate: Au, 2.526 oz. per ton; Ag, 7.5 oz.; Cu, 1.85%; Fe, 28.9%; Zn, 3.0%; Pb, 1.7%; insol., 31.0%.
Recovery: Au: flotation, 90%; cyanidation, 96%; overall, 86 to 88%.
Ratio of concentration: 12 : 1.
Water by gravity via pipe line 1 mi. from creek; CONSUMPTION, 4.72 tons per ton of feed, no reclamation.
Power: Generated at 440-volt by Diesel unit at plant; motors, 440-volt 60-cycle; CONSUMPTION, 23.6 hp-hr. per ton milled.
Labor: Native with American shift bosses; 4.45 tons per man-shift, operating; 12.52 tons per man-shift, repairs.
Running time: Crushing, 87% on 2-shift basis; grinding and flotation, 98%; cyanidation, 100%. Principal causes of lost time are routine repairs.
Mill building: Sloping site. Wood frame with galvanized-iron cover, wood and concrete floors. Unheated.
Machinery handling: Chain blocks throughout except for an electric hoist on a hand-operated traveling beam in the grinding department.
Tailing disposal: Run directly to Suyoc River.
Transport distances: 1 1/4 mi. mine to mill by truck. Concentrate directly to cyanide plant.



Legend for Fig. 62:

1. Bin; belt feeder.
2. 2 grizzlies in parallel.
3. 2 @ 8×16-in. single-toggle crushers in parallel.
4. Wash trommel.
5. 1 @ 2-ft. standard cone crusher.
6. Drag classifier.
7. 1 @ 5×8-ft. Eimco ball mill with 1/4-in. trunnion trommel.
8. 1 @ 230-ton bin with belt feeder.
9. 1 @ 13-ft. duplex bowl-rake classifier.
10. As (7).
11. 1 @ 6×6-ft. (square) pyramidal classifier.
12. 3 @ 30-in.×20-ft. corduroy tables in parallel.
13. 1 @ 4×7-ft. Wilfley table.
14. 2 amalgamating pans.
15. Bucket elevator.
16. 2 as (11) in series.
17. 1 @ 3-ft. simplex rake classifier.
18. 1 @ 4×4-ft. ball mill.
19. 1 @ 9×9-ft. conditioner, 172 r.p.m., 23 min. at 19% solids, *p*H 7.9 to 8.1; 230 t.p.d.; 2.1% >80-m., 81% <200-m.; assay: 0.11% Cu, 3.9% Fe, 0.20% Zn, 0.84% Pb, 3% CaO, 85% SiO_2, 0.236 oz. Au.
20. 2 @ 56-in. Fagergren cells in series, 580 r.p.m., rubber-covered impeller and cage, 12 hp. motors; about 13 1/2 min. time-factor through (20), (21), (22); 18% solids; *p*H 7.8. Concentrate: 1.85% Cu, 3.0% Zn, 1.70% Pb, 28.9% Fe, 2.526 oz. Au; tailing, 0.043 oz. Au.
21. 4 as (20).
22. 2 as (20).
23. 4 tables as (12).
24. 1 @ 14-ft. thickener; 1 @ 4-disk 4-ft. American filter.

FIG. 62. SUYOC CONSOLIDATED MINING CO.

Summary. Two-stage crushing; 3-stage grinding (first stage open-circuit) with gravity concentration in the grinding circuit. Gravity concentrate amalgamated. Flotation by a rougher-scavenger routing with rejection of tailing and cyanidation of concentrate.

Flotation + cyanidation of tailing

This treatment is practiced when there are sulphide or other floatable cyanicides in the ore (*e.g.*, sulphides of copper, arsenopyrite, pyrrhotite, bismuth, carbonaceous matter), or the gold is in both sulphides and gangue but that in the gangue is relatively coarse while that in the sulphides is relatively fine. Concentrate may also be cyanided after removal of cyanicides, as by roasting.

A. S. and R. Co., Octave mine. Fig. 63 (*6991 IC 15*).

Location: Octave, Ariz.
Ore: Gold with galena, chalcopyrite, bornite, and pyrite in quartz veins in granodiorite.
Capacity: 90 to 100 tons per 24 hr.
Assays: Feed, 0.3 oz. Au per ton; concentrate, 12.5 oz. Au and 15 oz. Ag; Pb, 8.5%; Cu, 1%. Flotation tailing, 0.05 oz. Au.
Recovery: By flotation: Au, 83.6%; Ag, 74%; Pb, 80%; Cu, 80%. By cyanidation: Au, 11.4%; Ag, 10.5%. Total, Au, 95%; Ag, 84.5%.
Ratio of concentration: 35 to 45 : 1.
Water piped 8 mi. by gravity.
Power: Purchased at 44,000 volts; motors, 440-volt.
Labor: 9 to 10 tons per man-shift.
Millsite steeply sloping.
Transportation: Mine at mill. Nearest railroad, 12 mi.
Costs (1935): Labor, $0.52 per ton; supplies, 0.44; power, 0.60; reagents, 0.24; hauling concentrate, 0.07; maintenance, 0.25; superintendence and royalty, 0.10; total, $2.22.

Legend for Fig. 63:
1. Feed sledged through 6-in. grizzlies on 2 @ 120-ton bins.
2. Grizzly, 1-in. spacing.
3. 1 @ 9×16-in. jaw crusher, 3/4-in. open setting.
4. Belt conveyor, +18°; 60-ton bin with belt feeder.
5. 1 @ 6×6-ft. ball mill, manganese-steel liners (life about 9 mo.), 12,000 lb. @ 4-in. steel balls (4.5 lb. per ton).
6. Duplex rake classifier; overflow <80-m., 75% <200-m.
7. 1 @ 6-cell mechanically agitated flotation machine; *a* = cell 1, *b* = cell 2, *c* = cell 3, *d* = remainder.
8. Thickener; 2×4-ft. drum filter; drying floor.

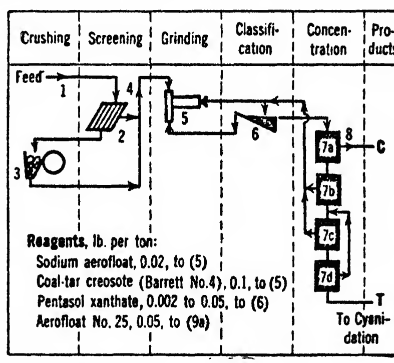


Fig. 63. A. S. & R. Co., Octave mine.

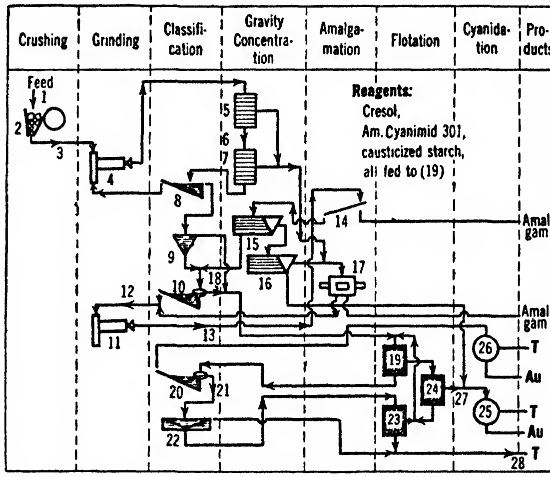
Summary. One-stage crushing and one-stage grinding to 80-m. Flotation (rougher-scavenger routing with middling regrind) makes 88% of the total recovery. Flotation tailing (the copper minerals having been removed) is cyanided by agitation without further grinding.

Idaho Maryland Mines Corp. Fig. 64 (*Q* by H. E. Viets).

Location: Grass Valley, Calif.
Ore: Gold and about 2% of sulphides (pyrite, 90%; galena, 5%; chalcopyrite. 3%; sphalerite, 2%) in gangue comprising quartz (50 to 65%) and a wall rock consisting of 20 to 30% carbonates; 40 to 50% hornblende, feldspar, chlorite, and sericite; and 15% of talcy materials.
Capacity: 400 tons per day (for the Idaho plant of which the flowsheet is given; additional ore, amounting to 200 t.p.d., is milled at the Brunswick and Forbestown mills).
Assays: Feed, $25 per ton ($35 gold); tailing, 50¢ to $1.
Recovery: 98%.
Water: Purchased. Approximately 15 tons in circuit per ton of ore milled; none re-used.
Power: Purchased. Transmitted at 4,000 volts; motors, 440-volt, 60-cycle. 2.4 connected hp. per ton milled.
Labor: American. 23 tons per man-shift operating; 400 tons, repairs.
Running time: 95%. Principal cause of loss is ball-mill relining.
Mill building: Sloping site. Wood frame, corrugated iron enclosure; cement floors, 1/2 in. per ft. slope. Heated.
Distances: Mine to mill, 0.9 mi., truck transport. Railroad on property.

Summary. One-stage open-circuit crushing and two-stage closed-circuit grinding to 100 *mog*, with Hungarian riffles in the primary circuit and shaking tables in the secondary circuit. Plate amalgamation of primary pulp, and barrel amalgamation of riffle concentrate



Legend for Fig. 64:

1. 200-ton shaft bin.
2. 18×30-in. Blake crusher, 4-in. open setting.
3. 200-ton bin; truck to mill; 750-ton mill bin; 5 Challenge feeders; 18-in. conveyor.
4. 1 @ 8×6-ft. Marcy ball mill.
5. 40-sq. ft. Hungarian riffles.
6. 4-in. Wilfley pump.
7. 175-sq. ft. Hungarian riffles.

24. 6 Kraut flotation cells: 900 r.p.m., rubber-covered impeller lasts 4 yr., cast-iron bell, 4 yr.; 7 1/2-hp. motors. Feed, 17% solids, *p*H 8.6; concentrate, 4 oz. Au, 3 oz. Ag per ton; tailing, 0.03 oz. Au.
25. Regrinding and cyanidation.
26. Sand leaching.
27. Thickening and filtration.
28. 0.03 oz. Au, 0.1 oz. Ag.

FIG. 64. IDAHO MARYLAND MINES CORP.

and table gold streak. Rougher-scavenger routing with intermediate desanding and thickening; one cleaning with one-stage counterflow of cleaner tailing. Flotation sand tailing sand-leached and all sulphide concentrate reground and slime-leached.

Mammoth-St. Anthony, Ltd. Fig. 65 (*Q* by Foster S. Naething).

Location: Mammoth, Ariz.
Ore: Cerussite, anglesite, wulfenite, mohramite, psilomelane, smithsonite, vanadinite, chrysocolla, descloizite, iron oxides, barite, calcite, feldspar, quartz, with gold and silver.
Capacity: 550 to 600 tons per 24 hr.
Assays: See Table 48.
Recovery: Au, 90%; Ag, 35%; MoO_3, 85%; V_2O_5, 55%.
Ratio of concentration: 36 : 1.
Labor: American and Mexican. Tons per man-shift: operating, 35; repairs, 50.
Running time: 98.5%. Loss due principally to power failure, pump repairs, ball-mill relining.
Water: Mine water pumped 1/2 mi. at a consumption of 100 hp. CONSUMPTION, 2.0 tons per ton of ore milled.
Building: Timber frame, corrugated-iron cover, concrete and wood floors sloping 1/8 in. per ft. in wet parts. (Floors stay dry except where there is continual leakage.) Occasional heating by stoves. Site level.
Machinery handling: Chain blocks.
Power: Purchased. Comes 50 mi. at 44,000 volts. Motors, 440-volt 60-cycle. CONSUMPTION: 25 hp-hr. per ton milled.
Transportation: Nearest railroad, 25 mi. Ore transported 1/2 mi. by motor truck; concentrate trucked 1 mi. to smelter.
Tailing: Pumped through 5-in. pipe to dam and discharged onto face through 2-in. pipes spaced 5 to 18 ft. apart along 5-in. main.

Summary. Crushed from run-of-mine (small head-size) to <8-m. table feed by gyratory, short-head cone and rod mill in series, the latter in closed circuit with a vibrating screen. Table tailing ground to 10% >65-m., 50% <200-m. in one ball mill in closed circuit with a rake classifier. A table concentrate is scalped out of the 8-m. rod-mill product by shaking tables, which return middling to the rod-mill circuit and send tailing to the ball-mill circuit. Flotation is essentially by two successive circuits on rougher-cleaner flows with one cleaning of gold concentrate, two cleanings of oxide concentrate. Sand tailing is cyanided.

Flotation ± gravity concentration and/or amalgamation

This flowsheet is followed today at a large number of gold mills. The method is primarily applicable to ores in which the gold occurs in the sulphides, and the latter have independent value (Cu, Pb, Zn, etc.) or are not amenable to cyanidation. The method is, however, also used at small mines, or mines in the development stage, for ores amenable to cyanidation, when the more elaborate and expensive cyanide equipment is not justified or not within reach of the owner's purse. (A cyanide plant for a small daily tonnage costs two to three times as much as a simple concentration or amalgamation plant, and not infrequently the bulk of the gold is freed at 48 to 65 *mog.*)

Gold-flotation flowsheets vary tremendously in detail, but broadly gravity concentration ± amalgamation precedes flotation when a part of the gold is coarse or the sulphides are coarsely dispersed, whereas with fine gold and fine sulphides all concentration is done by flotation; occasional coarse valuable particles in such an ore can be taken care of by a jig or table scavenging flotation tailing.

Small plants comprise one-stage crushing and one-stage closed-circuit ball milling to flotation size. For tonnages in excess of 150 t.p.d. practice tends to make ball-mill feeds <3/8-in. maximum. In general this will require a second crushing stage, usually in closed circuit with a screen. Flotation flowsheets depend upon the disposition of concentrate; if this is to be cyanided, or shipped a short distance only, recovery is more important than grade and a simple rougher-scavenger flow is used; if freight and treatment charges are high, grade becomes important and the rough concentrate is usually cleaned once or twice with one-stage counterflow of cleaner tailing. Gravity concentration (jigs, blankets, or tables) is inserted in the grinding circuit if free gold or gold-bearing sulphide in appreciable quantities is present at sizes coarser than 65-m. Blankets are placed in tailing launders at Britannia and at Utah Copper Co. to scavenge minute amounts of gold not saved in the regular copper flotation.

Golden Belt Mines, Inc. Fig. 66 (*IC 6905*).

Location: Near Cleator, Yavapai County, Ariz.

Ore: Stringers of pyrite and galena, and of quartz with disseminated sulphides in schist. Not amenable to cyanidation or amalgamation. Gold follows galena.

Capacity: 50 tons per 24 hr.

Assays (one day): Feed, 0.21 oz. Au, 2 oz. Ag; concentrate, 2.62 oz. Au, 19.7 oz. Ag, 14.2% Pb; tailing, 0.01 oz. Au, 0.31 oz. Ag.

Recoveries (average): Au, 95%; Ag, 80%.

Ratio of concentration (one month): 14.5 : 1.

Water is pumped from the mine.

Power is purchased on an 80-kw. demand basis at a sliding scale ranging from 2.5 to 1¢ per kw-hr. Comes in at 11,000 volts; 440-volt motors.

Mill building: Sloping site. Wood.

Transportation: Mill at mine. Concentrate sacked and trucked to El Paso, Tex., at $8.15 per ton (1936).

Costs (operating only): Labor, $0.57 per ton; supplies, 0.14; power, 0.31; total, $1.02.

Summary. Run-of-mine hand-picked for waste, crushed to 1- to 2-in. in one stage and ground to flotation-feed size in one stage closed-circuit. Flotation concentration by simple rougher-scavenger routing.

Legend for Fig. 66:

1. Ore from mine to 3-ton hopper.
2. 1 @ 16-in.×10-ft. picking belt, 21 f.p.m., 2-hp. motor. Two men sort one carload of ore in about 5 min. Rejection of waste is about 33%.
3. 1 @ 7×10-in. Blake crusher, set 1-in. (1.5-in. on wet ore), 15-hp. motor.
4. 1 @ 35-ton bin; Challenge feeder.
5. 1 @ 4×5-ft. ball mill, 4-in. balls.
6. 1 @ 6×20-ft. duplex drag classifier.
7. 4-cell flotation machine; *a* = first two cells.
8. Directly to 1 @ 1×4-ft. drum-type filter.

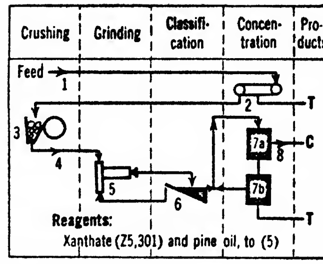

FIG. 66. GOLDEN BELT MINES.

This is about as simple a flowsheet as can be used on an ore not amenable to amalgamation. Smelter charge on concentrate is about \$5 per ton. Recovery is excellent.

Premier Gold Mining Co. Fig. 67 (*IC 6742*).

Location: Premier, B. C.
Ore: Auriferous pyrite with small amounts of lead, zinc, and copper in highly siliceous gangue.
Assays: See Table 49.
Recovery: Au, 96.7%; Ag, 87.7%. See also Table 50.
Ratio of concentration: 8.6 : 1.
Capacity: Tons per 24 hr., 450 to 475.
Water: Gravity flow from upper workings of mine; tons per ton of ore milled, net, 3.5.
Labor: 19 tons per man-shift, total.
Power: Company-generated, 1/2 mi. from mill; Diesel and hydroelectric; transmitted at 2,300 volts; motors, 440-volt. CONSUMPTION, hp-hr. per ton: Crushing, 5.0; grinding and classification 18.0; flotation, 8.3; filtering, 1.7; pumping, 7.8; lighting, 1.3; total, 42.1.
Costs: Cents per ton (1931): Crushing, 16.2; grinding and classification, 46.5; flotation, 18.0; filtering, 5.1; pumps, pipe lines, and launders, 9.0; lubricants, 0.9; lighting, 0.8; heating, 0.8; miscellaneous, 3.0; superintendence, 6.4; total, \$1.07.

Legend for Fig. 67:

19. Overflow from cells 1 to 4 of (17).

19*a*. Overflow from first machine of 18; 2-in. Wilfley pump.

20. 1 @ 12-ft. 2-spitzkasten K. and K. machine.
21. Froth from cells 5 to 24 of (17) and second machine of 18.
22. 1 @ 30-ft. thickener.
23. 1 @ 18-ft. thickener.
24. 1 @ 5 1/3×4-ft. and 1 @ 5 1/3×6-ft. Oliver filters.
25. 1 @ 30-ft. thickener

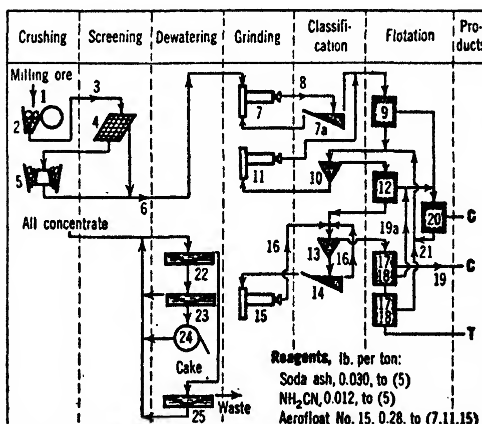

FIG. 67. PREMIER GOLD MINING CO.

Table 49. Assays at Premier

Material	Assays: Oz. per ton Au	Ag	Percentages Pb	Zn	Fe	Insol.
Feed	0.35	6.55	0.7	1.7	6.0	74.2
Concentrate	2.82	53.73	4.3	10.3	31.7	9.6
Tailing	0.013	0.91	0.2	0.6	2.6	82.6

Table 50. Sizing-assay test of concentrate and tailing at Premier

Material	>150-m. Wgt., %	Oz. per ton Au	Ag	150~200-m. Wgt., %	Oz. per ton Au	Ag	<200-m. Wgt., %	Oz. per ton Au	Ag
Concentrate	29.6	4.47	39.26	11.4	2.96	33.92	59.0	1.92	64.80
Tailing	12.9	0.021	0.98	12.6	0.022	0.90	74.5	0.013	0.81

Summary. Two-stage crushing to 1 1/2-in.; 3-stage grinding to 50-m. with flotation in the primary (2-stage) circuit. All-flotation concentration, four stages on the primary run with two regrinds on underflow and regrind of scavenger and cleaner middlings prior to return to the head of the primary circuit. The flow is interesting in that step removal of the gold permits definitely coarser over-all grinding (70% <200-m. *vs.* 81% <200-m.) than a flow without middling regrind. The coarser grinding has also been of marked benefit in concentrate dewatering.

London Mines & Milling Co. (*North London mill*). Fig. 68 (*7101 IC 34*).

Location: About 8 mi. west of Alma, Colo.

Ore: Auriferous pyrite and free gold with small amounts of galena and chalcopyrite in quartz veins in quartzite, porphyry, limestone, and carbonaceous shale; not amenable to cyanidation on account of the shale.

Capacity: 100 t.p.d.

Assays, oz. Au per ton: Feed, 0.32; concentrate: high-grade streak from tables, 43.0; remaining table plus flotation, 2.43; tailing, 0.023.

Recovery: 93.7%.

Ratio of concentration: 10.4 : 1.

Water comes by flume to foot of mill.

Power: Purchased at 13,000 volts: motors, 440-volt.

Labor: Tons per man-shift, total, 14.

Legend for Fig. 68:

1. R.o.m. <6-in., dumped by hand.
2. 1 @ 3×10-ft. trommel, 2 1/4-in. aperture.
3. 15-ton bin with sorting chute; 15 to 18% of ore mined rejected as waste.
4. 30-ton bin; 3,300-ft. aerial tram; 30-ton bin; hand-controlled chute feed to crusher (5).
5. 1 @ 10×16-in. jaw crusher, 1/2-in. set, 275 r.p.m., 30-hp. motor.
6. 100-ton bin; separate cars on aerial tram (4); surge bin.
7. Vibrating screen, 1 1/4-in. aperture; about 30% oversize.
8. 250-ton bin; oscillating feeder.
9. 1 @ 5×6-ft. cylindrical ball mill, 28 r.p.m., 100-hp. motor; 6,000 lb. 4-in. cast chrome-molybdenum steel balls and liners. Ball cost, 14.5¢ per ton milled.
10. Vibrating screen, 1/8×1/4-in. aperture.
11. 1 @ 3×15-ft. rake classifier, 200% circulating load.
12. 1 @ 2-in. centrifugal pump.
13. 2 Card tables in parallel, 270 s.p.m.
14. 1 Card table. The combined concentrates from (13) and (14) comprise 50 to 67% of all gold recovered.
15. 1 @ 3-in. centrifugal pump.
16. As (12).

18. As (14).

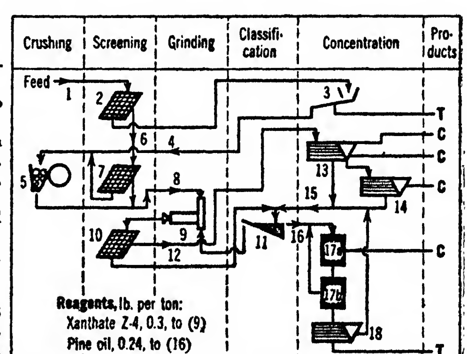

FIG. 68. LONDON MINES & MILLING CO.

Transportation: Mine to mill, 3,300 ft. by aerial tram; mill to smelter at Leadville by truck, \$4.50 per ton.

Costs, operating (1937): Labor, \$0.52 per ton mined; supplies, 0.24 (includes 14.5¢ per ton milled for grinding-steel and 7.8¢ for flotation reagents); repairs, 0.03; power, 0.18; total \$0.97.

Summary. One-stage crushing and one-stage grinding to flotation-feed size, with high-grade concentrate scalped out of the grinding circuit by tables. Flotation concentration by a simple rougher-scavenger routing.

Cardinal Gold Mining Co. Fig. 69 (*IC 7012*).

Location: Bishop Creek, Calif.

Ore: Gold in arsenopyrite and wollastonite, associated with small amounts of pyrrhotite, pyrite, chalcopyrite, and sphalerite in a tough, hard garnetiferous quartzite. Amalgamation, and tabling plus cyanidation of tailing have both proved unsuccessful.

Capacity: 300 tons per 24 hr.

Assays: See Table 51.

Recovery: Au, 90%.

Ratio of concentration: 32 : 1.

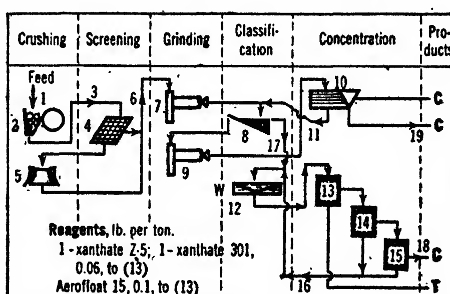
Labor: 30 tons per man-shift, total.

Transportation: Mill at mine. Concentrate trucked 23 mi. to Laws, Calif., at \$2.50 per ton; thence by narrow-gage to Mina, Nev., and by standard-gage to Midvale, Utah, at an additional cost of \$10.70 to \$12.50 per ton, according to grade. Total concentrate liquidation charges amounted (1937) to \$1.37 per ton of ore milled.

Costs (June, 1937): Labor, \$0.33 per ton milled; power, 0.28; supplies, 0.21; maintenance, 0.33; miscellaneous, 0.09; total, \$1.24.

Table 51. Assays at Cardinal mill

Material	Assays						
	Oz. per ton		Percentages				
	Au	Ag	Cu	Fe	Zn	S	Insol.
Feed	0.27	....	....	....	....	....	....
Table conc.	115.0	22.5	0.3	38.3	0.4	16.2	4.0
Flotation conc.	6.9	1.7	1.8	36.3	0.5	24.2	12.8
Tailing	0.03	....	....	....	....	....	....



Legend for Fig. 69:

1. 2 @ 15-ton wooden skip pockets; 1 @ 36-in. pan conveyor.

2. 1 @ 10×24-in. Blake-type jaw crusher, set 4-in.

3. 1 @ 20-in. belt conveyor; pancake suspended magnet.

4. 1 @ 2×8-ft. Jeffrey-Traylor 60-cycle vibrating grizzly, 1-in. aperture.

5. 1 @ 20-in. Traylor TY reduction gyratory, set 1/2-in.

6. 1 @ 20-in.×220-ft. inclined (18°) belt conveyor; 2 @ 250-ton laminated-wood bins.

7. 1 @ 4×10-ft. rod mill, 12 tons @ 4-in. rods, manganese-steel liners.

8. 1 @ 6×24-ft. rake classifier; overflow, 4.5% >100-m., 61% <200-m.

9. 1 @ 5×6-ft. overflow-type ball mill, 4 to 5 tons @ 4-in. pressed-steel balls, manganese-steel liners.

7–9. In a parallel one-stage grinding circuit 1 @ 7×6-ft. A-C grate-type mill is in closed circuit with a 6×23 1/2-ft. heavy-duty rake classifier. A trunnion trommel with 1/8-in. sq.-m. cloth scalps oversize to the classifier while undersize goes to a table (10), which returns tailing to the classifier. Classifiers are cleaned out once a month and the sands tabled, yielding about 20 oz. of gold each in a high-grade concentrate.

10. 2 shaking tables in parallel (1 for each section). The high-grade streak runs 110 to 120 oz. Au and 20 to 25 oz. Ag per ton; the middling streak is maintained at about 10 oz. Au per ton; combined concentrates contain about 40% of recovered Au.

11. 2 @ 2-in. Wilfley pumps.

12. 1 @ 30×10-ft. thickener; underflow, 40 to 45% solids. Gold content in flotation tailing rises from 0.02 oz. per ton at 40% solids in feed to 0.065 oz. at 15% solids.

13. 4 @ 56-in. square Fagergren cells in series.

14. 1 @ 45-in. square Fagergren cell.

15. 2 @ 36-in. square Fagergren cells in series.

16. 1 @ 2-in. Wilfley pump.

17. 1 @ 3-in. rubber-lined Hydroseal pump (Unit 1) and 1 @ 2-in. Wilfley pump (Unit 2).

18. 1 @ 12×8-ft. thickener; 1 @ 2-leaf 4-ft. American filter; 1 @ 3-compartment steam drier to 10 to 12% moisture.

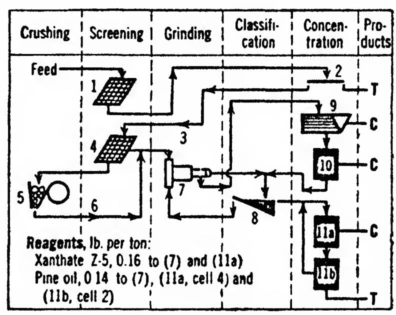
19. Combined with thickener (18) underflow.

Fig. 69. Cardinal Gold Mining Co.

Summary. Two-stage open-circuit crushing and two-stage grinding (first stage open-circuit, second closed) with tabling between stages. Rougher and 2-stage cleaner flotation.

St. Joe Mining & Milling Co. Fig. 70 (*IC 6976*).

Location: Rowena, Colo.
Ore: Tellurides of gold and silver closely associated with pyrite and some native metal, together with minor amounts of marcasite and arsenopyrite in a gangue of quartz and iron oxides.
Capacity: 90 tons per 24 hr.
Assays: Feed, 0.219 oz. Au and 0.366 oz. Ag per ton; concentrate, 2.851 oz. Au and 3.013 oz. Ag; tailing, 0.021 oz. Au and 0.167 oz. Ag.
Recovery: Au, 91.0%; Ag, 57.7%.
Ratio of concentration: 14.3 : 1.
Water consumption: 4 tons per ton of ore.
Power consumption: 28 hp-hr. per ton of ore.
Labor: 7.2 tons per man-shift, total.
Running time: 87%.
Transportation: Feed is trucked 8 mi. over a steep dirt road at a cost of 75 to 85¢ per ton; concentrate (10 to 12% moisture) is trucked 21 mi. to the railroad at Boulder, thence by rail 110 mi. to Colorado City or 150 mi. to Leadville; freight rates range from $1.50 to $5.00 per ton according to destination and value of concentrate.
Costs: $1.69 per ton of ore milled.



Legend for Fig. 70:

1. Grizzly with 2-in. spacing over mine bin.
2. Sorting floor over mine bin; about 10% wash removed.
3. 8-mi. truck haul to mill; 3 @ 80-ton bins with 12-in. guard grizzlies.
4. Grizzly chutes from bins, 3/4-in. spacing.
5. 1 @ 13×24-in. high-speed jaw crusher, set 3/4-in.; 360 r.p.m., 35-hp. motor.
6. 1 @ 18-in.×130-ft. conveyor; 4-ft. Snyder sampler; 300-ton bin with 24-hr. apron feeder, 4 1/2 f.p.m.; 1 @ 12-in. belt conveyor.
7. 1 @ 5×8-ft. ball mill with 6-m. 13(diam.)×18-in. trunnion trommel, 29 r.p.m., 125-hp. motor, 4-in. forged-steel balls.
8. 1 @ 4 1/3-ft. duplex drag classifier; overflow <80-m.
9. 2 shaking tables; concentrate represents 10 to 15% recovery.
10. Unit flotation cell; concentrate represents 45% recovery.
11. 1 @ 8-cell flotation machine; *a* = cells 1 to 4; *b* = cells 5 to 8.

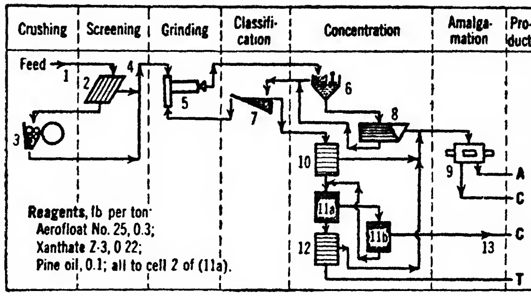
FIG. 70. ST. JOE MINING & MILLING CO.

Summary. One-stage crushing and one-stage grinding to 80-m. with gravity concentration and rough flotation in the grinding circuit. Final flotation by simple rougher-scavenger routing.

Golden Anchor Mining Co. Fig. 71 (*IC 7024*).

Location: Burgdorf, Idaho.
Ore: Native gold and tetrahedrite, galena, sphalerite, pyrite, and molybdenite in quartz, with schist, gneiss, and quartzite wall rock.
Capacity: 50 tons per 24 hr.
Assays (1937): Feed, 0.711 oz. Au and 2.58 oz. Ag per ton; tailing, 0.0488 oz. Au, 0.67 oz. Ag. Flotation concentrate, Au, 36.4 oz.; Ag, 53.8 oz.; Pb, 4.5%; Cu, 1.3%.
Recovery: Gold, by amalgamation, 75.6%; by flotation, 17.4%; total, 93.0%; silver, 80.7% total.
Ratio of concentration: 272 : 1.
Power: Company-generated by Diesel unit; transmitted 4 mi. at 2,200 volts, cost 1.6¢ per kw-hr.; motors, 440-volt; consumption, 30.2 kw-hr. per ton milled.
Labor: 13.5 tons per man-shift, total.
Transportation: 50 mi. from railroad; road closed to wheeled traffic 5 winter months. Mill at mine. Concentrate trucked 567 mi. to smelter at Garfield, Utah, at cost of $26 per ton.
Costs (1937): $2.70 per ton milled, including overhead and realization amounting to 89¢ per ton.

Summary. One-stage crushing and one-stage grinding to 65 *mog* with rougher-cleaner gravity concentration in the grinding circuit; ground product straked, floated, and straked, with one-stage cleaning of rough flotation concentrate. Gravity concentrate amalgamated.



Legend for Fig. 71:

1. R.o.m. sledged through 8-in. grizzly on 50-ton bin.

2. Grizzly, 3/4-in. spacing.

3. 1 @ 8 × 24-in. A-C jaw crusher, set 1/2 in., 230 r.p.m.

4. 50-ton bin; 15-in. × 6-ft. belt feeder, 18 in. per min.

5. 1 @ 4 1/2 × 5-ft. overflow-type ball mill, wave-type liners, 3-in. forged-steel balls (3.6 lb. per ton), 32 r.p.m.

6. 1 @ 12 × 18-in. Denver mineral jig, 300 pulsations per min., 2-in. bed of 3/8-in. ball bearings; about 15 lb. of hutch concentrate drawn once each shift.

7. Akins classifier, 5 1/2 r.p.m.

8. Half-size Wilfley table.

9. Amalgam barrel, run as sufficient concentrate accumulates, usually about twice per month. Charge is ground 6 hr. with Hg, lye, and about 12 @ 4-in. steel balls. Amalgam retorted; residue (assays about 14 oz. Au per ton) is shipped to smelter.

10. 3 @ 11-in. × 12-ft. strakes (slope, 1 1/4 in. per ft.) in parallel, covered with rubber matting; cleaned every 2 da.

11. 1 @ 6-cell No. 15 Denver Sub-A flotation machine, fed into a conditioner cell 2; *a* = cells 2 to 6; *b* = cell 1.

12. 1 @ 11-in. × 12-ft. rubber-mat strake.

13. 36-in. cone discharged by hand-operated diaphragm pump to a pressure filter. Cake 10% moisture; dried in pans and sacked.

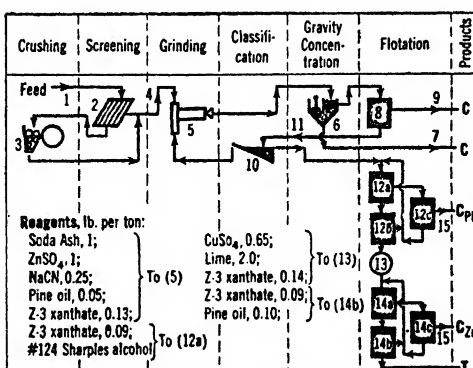
FIG. 71. GOLDEN ANCHOR MINING CO.

Pride of the West mill. Fig. 72 (*Tref 3/41*).

Location: Howardsville, San Juan District, Colo.

Ore: Gold and silver, free and associated with galena; tetrahedrite, chalcopyrite, pyrite, and sphalerite, with quartz, chalcocite, and altered andesite. The tetrahedrite carries considerable silver; the pyrite is relatively free of precious metals.

Capacity: 50 tons per 24 hr.



Legend for Fig. 72:

1. 5-ton trucks; 8-in. limiting grizzly; 50-ton bin.

2. 1 @ 2 × 5-ft. grizzly, 1 1/4-in. spaces; oversize discharge controlled by Ross chain, 1/2-hp. gear motor, capacity 9 t.p.h.

3. 1 @ 9 × 16-in. single-toggle jaw crusher, 1-in. open setting. Operates 1 @ 8-hr. shift; one man on grizzly and crusher.

4. 1 @ 14-in. × 65-ft. belt conveyor, slope 4 3/4 i.p.f., 150 f.p.m., 2-hp. motor; 1 @ 160-ton bolted-steel bin; 1 @ 16-in. × 14 1/4-ft. belt feeder, slope 3 i.p.f., 1-hp. motor with reducing gear (50 : 1), 10 f.p.m.

5. 1 @ 5 × 5-ft. ball mill with 18 × 30-in. trunnion screen, 0.13-in. opening; 25.3 r.p.m.; 50-hp. 900-r.p.m. synchronous motor; 70% solids; feed, 23.9% >1-in.; screen oversize, 9% >1-in., 0.3% <6-m.; undersize, 3.5% >20-m., 14% <200-m. Forged-steel balls, 2.3 lb. per ton.

6. 1 @ 8 × 12-in. Denver mineral jig; concentrate 3.9 oz. Au, 15.1 oz. Ag, 82.8% Pb, 0.8% Zn; recovery of gold, 59.5%.

7. Concentrate: 3.9 oz. Au, 15.1 oz. Ag, 83% Pb, 0.8% Zn; 60% recovery of gold; 1.2% >10-m., 8.3% <65-m.

8. 1 Denver No. 250 unit cell, 5-hp. motor. 4 tons concentrate per day.

9. Concentrate: 0.1 oz. Au, 15.0 oz. Ag, 69.5% Pb, 2.5% Zn, 1.1% insol.; 13.7% recovery of gold; 0.9% >65-m., 75% <200-m.

10. 1 @ 30-in. Akins classifier, slope 4 in. per ft., 8 r.p.m., 2-hp. motor. Sand: 5% >14-m., 26% <100-m., 0.07 oz. Au, 2.75 oz. Ag, 5% Pb, 4.9% Zn, 7% Fe. Overflow, 34% solids, 0.02 oz. Au, 2.1 oz. Ag, 4.3% Pb, 4.6% Zn; 2.1% >65-m., 60% <200-m.

11. 2.2% >28-m., 15.3% <200-m.

12. 1 @ 6-cell No. 18 (28 × 28-in.) Denver Sub-A flotation machine, 3 @ 2-hp. motors. 12*a* is cell 2; 12*b* is cells 3 to 6; 12*c* is cell 1.

13. 1 @ 6 × 6-ft. conditioner, 8-hp. motor, 25% solids, 40 min. contact.

14. As (12).

15. 1 @ 4-ft. 4-leaf American filter, 3/4-hp. motor. 3 leaves for Pb, 1 for Zn.

FIG. 72. PRIDE OF THE WEST.

Assays: See Table 52.
Recovery: Au, 87.8%; Ag, 81.5%; Pb, 96.4%; Zn, 68.8%.
Ratio of concentration: Pb, 6.2 : 1; Zn, 20 : 1.
Power: Purchased. Comes in at 17,000 volts; motors 440- and 220-volt. Cost: \$6.50 per peak-load hp. per mo.
Water pumped against 100-ft. head from a nearby creek.
Mill building: Slightly sloping site. Wood frame, siding insulated and covered with galvanized sheet steel. Concrete foundations and floors. Heated.
Cost: \$1.75 per ton milled.

Table 52. Assays at Pride of the West mill

Material	Assays				Weight, %
	Oz. per ton		Per cent.		
	Au	Ag	Pb	Zn	
Feed.........	0.06	3.3	10.4	4.3	100.0

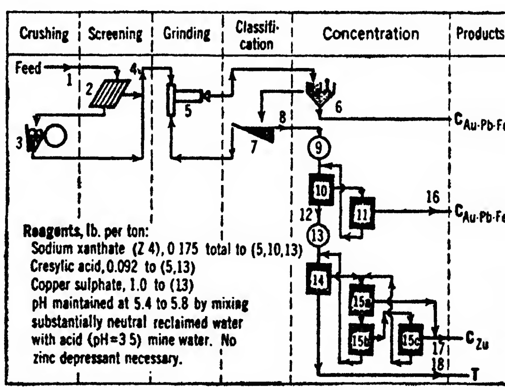
Summary. One-stage open-circuit crushing and 1-stage closed-circuit grinding from 8-in. to 48 *mog.* Jig and unit cell in series in grinding circuit. Standard Pb-Zn differential flotation with one cleaning.

Tennessee-Schuylkill Corp. Fig. 73 (*IC 7077*).

Location: Chloride, Ariz.
Ore: Galena, sphalerite, auriferous pyrite, and small amounts of arsenopyrite and chalcopyrite in quartz and soft altered wall rock (diorite gneiss, granite, quartz-monzonite porphyry, rhyolite, diabase). Relatively soft for crushing and grinding.
Capacity: 150 to 175 tons per 24 hr.
Assays, recoveries, ratios of concentration: See Table 53.
Water: From mine, highly acid; CONSUMPTION, 1.6 tons per ton of ore, net.
Power: Purchased at 44,000 volts; price, 1.6¢ per kw-hr.; motors, 220- and 440-volt; 291.5 total connected hp.
Labor: 15 tons per man-shift operating.
Transportation: Mill at mine. Concentrate trucked 22 mi. to Kingman, Ariz., at contract price of \$1.50 per ton (1938), including loading and unloading. Rail freight on lead concentrate from Kingman to El Paso, Tex., \$5.50 per ton for \$40 concentrate; on zinc concentrate the rate to Amarillo, Tex., is \$5.15 for \$30 concentrate. Jig concentrate (value \$630 per ton) is shipped separately to El Paso at \$10 per ton.
Costs (1938): Crushing, \$0.154 per ton; grinding and classifying, 0.404; flotation, 0.392; general, including taxes and insurance, 0.955; total, \$1.905.



Legend for Fig. 73:

25. 500-ft. launder to 1,000-ft. ditch to 3 settling ponds in series; overflow to clarifying pond, 300 sq. yd. area, overflow slightly "milky."

FIG. 74. ST. JOSEPH LEAD CO., Atlanta mill.

Power: Diesel with auxiliary hydroelectric. CONSUMPTION: Crushing, 41 hp.; grinding, 135; flotation, 37; filtering, 7; misc., 10.

Water: From local stream by gravity. CONSUMPTION, 85 to 100 g.p.m.

Labor: Tons per man-shift 10.94.

Transportation: Trammed from haulage adit to mill bin. Concentrate trucked 85 mi. to rail at Mountain Home, Idaho, during summer, thence to Garfield, Utah. In winter bullion is shipped out by plane 60 mi. to Boise, Idaho; concentrate is stored until summer.

Cost, $ per ton: Crushing, 0.10; grinding, 0.49; amalgamation, 0.08; flotation, 0.26; filtering, 0.07; tailing disposal, 0.06; misc., 0.06; superintendence, 0.04; total, $1.16.

Summary. Crushing by jaw crusher and two stages of rolls, the last in closed circuit with 0.5-in. screen. Grinding in two stages, the first open-circuit, the second closed-circuit, with plate amalgamation in both circuits. All-flotation concentration by a rougher-scavenger flow on the primary run, with two cleanings of rough concentrate and counterflow of cleaner middlings to the primary rougher.

Alaska Juneau Gold Mining Co. Fig. 75 (*Q* by J. A. Williams, Gen'l Sup't; *IC 6236; 133 J 475*).

Location: Juneau, Alaska.

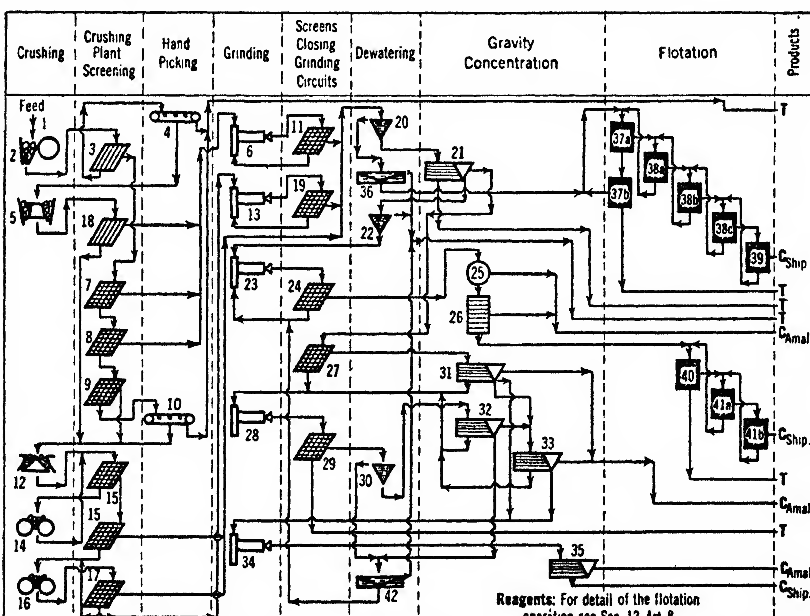
Ore: Gold, galena, sphalerite, and pyrite in quartz stringers in slate and metagabbro.

Capacity: 13,200 t.p.d. to sorting plant, 50% rejected, balance milled.

Assays: Mine product, $1.16 ($35 gold) per ton; residue milled after coarse sorting, $2.14 per ton; concentrates: table, 8.285 oz. Au, 43.79 oz. Ag, 52.2% Pb; flotation, 10.11 oz. Au, 23.44 oz. Ag, 24.27% Pb.

Recovery: 78.03% based on gold sent to sorting plant; 86.73% on milling heads. Ratio of concentration: 1,024 : 1 on feed milled.

Water: Fresh water by flume, supplemented by 4 @ 10-in. pumps (1,650 connected hp., 13,000 g.p.m. rated capacity) through 20-in. wood-stave line. Salt water used as required, mostly in cold weather. Water CONSUMPTION, approximately 10 tons per ton milled, none re-used.



Legend for Fig. 75:

1. Passing 27-in. grizzly. 2 @ 4-car revolving tipples; 1,500-ton (live) tipple hopper; 6 @ 60-in. apron feeders.

2. 3 @ 36×48-in. Buchanan jaw crushers, 8-in. open setting (2 operating, 1 reserve) 166 r.p.m., 150-hp. motors.

3. 3 @ 5-ft. bar grizzlies, 4-in. spacing (2 operating, 1 reserve).

4. 3 @ 42-in. sorting belts (2 operating, 1 reserve), 100 f.p.m., placed over bowl of gyratory (item 5) so that ore pulled off falls directly into gyratory. Heavy spray washes rock as it comes onto belt. 4 men on each belt remove 70 to 80

FIG. 75. ALASKA JUNEAU GOLD MINING CO.

Legend for Fig. 75—Continued:

tons each per man-shift. Selection involves only separation of quartz and part-quartz pieces from dark gangue.

5. 3 @ 9 K gyratory crushers, 2-in. open setting, 150-hp. motor.

6. 12 @ 8×6-ft. ball mills.

40. 1 @ 6-cell Denver Sub-A machine.

41. 1 @ 6-cell Denver Sub-A machine; *a* = cells 4 to 6; *b* = cells 1, 2.

42. 3 thickeners.

Power: Hydroelectric; steam reserve. Transmitted 12 mi. at 22,000 volts. Motors 110- and 2,300-volt 60-cycle. Consumption, 19.1 hp-hr. per ton milled.

Labor: American, 48.22 tons per man-shift operating.

Running time: 97.5%. Principal causes of loss are blockholing and power failure.

Mill building: Exceptionally steep sloping site. Concrete and steel, concrete floors sloping 1/2 in. per ft. Heated in freezing weather.

Machinery handling: Inclined tram from dock to various mill benches; 20-ton traveling power crane on coarse-crushing bench; 50-ton on fine-crushing bench; monorail crane and crawls on concentrator bench.

Distances: Mine to mill, 2 mi.; electric haulage in trams of 4 @ 10-ton cars. Steamship dock within a few hundred feet of mill. Concentrate shipped 2,000 mi. by boat.

Tailing disposal: Fine tailing lifted about 40 ft. by 5 to 6 out of 7 @ 8-in. Wilfley pumps to a tail-flume open penstock and thence by gravity into bay; coarse waste trammed in side-dump cars, thence by conveyor to scow which is towed by tug into deep water and dumped.

Summary. Five-stage crushing and one coarse-grinding stage from 27-in. r.o.m. to <7-m. table feed. Half of mill feed rejected by hand sorting, and a second large rejection made on deslimed <7-m. primary feed on roughing tables. Rougher-table concentrate reground and reconcentrated in three successive table-cleaning stages. Rougher-table middling reground and floated with rejection of tailing and 2-stage cleaning. Primary fines floated with rougher-scavenger flow on the primary run and four successive cleanings with 1-stage counterflows of cleaner tailings.

This flowsheet is unique in that it is substantially the application of placer-gold treatment to a lode ore of a grade that rivals placer deposits in the meagerness of gold and heavy-mineral content. It is a going project economically only because of the enormous rejections of tailing before the relatively expensive operations of grinding and flotation need be applied to the enriched residues.

A. S. & R. Co., Alice unit. Fig. 76 (*IC 7058*).

Location: Alice, Colo.

Ore: Auriferous copper minerals (secondary sulphides and malachite), silver, chalcopyrite, and pyrite in quartz and siderite. About 80% of value is Au, 20% Ag and Cu.

Capacity: 200 tons per 24 hr.

Assays: Feed, 0.12 oz. Au and 0.70 oz. Ag per ton, 0.4% Cu; concentrate: table, 0.8 oz. Au, 8 oz. Ag, 7% Cu; flotation, 1 oz. Au, 15 oz. Ag, 10% Cu; tailing, 0.015 oz. Au and 0.20 oz. Ag.

Recovery: Au, 82%; Ag, 70%; Cu, 70%.

Ratio of concentration: 22 : 1.

Water piped by gravity 1 mi. from a creek.

Power purchased; comes in at 23,000 volts; motors, 440-volt. Cost, 1.33¢ per kw-hr.

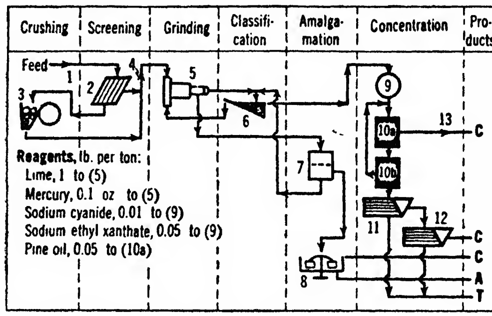
Labor: 22 tons per man-shift, total.

Millsite: Steeply sloping.

Transportation: Mill at mine. Concentrate trucked 12 mi. to Idaho Springs, thence by narrow-gage and standard-gage railroad to Garfield, Utah, at a cost of about $6 per ton, total.

Costs (1936): Labor, $0.38 per ton; supplies, 0.15; power, 0.07; total direct operating, $0.60.

Summary. One-stage crushing and one-stage grinding to 20-m. with amalgamation (making 70% of total recovery) in the grinding circuit. Flotation (rougher-scavenger routing) followed by tabling for the remaining recovery.



Legend for Fig. 76:

1. 1 @ 70-ton bin with vibrating feeder; 1 @ 30-in.×15-ft. belt conveyor (tramp iron picked by crusherman).

2. Grizzly (3 ft. long), 2 1/2-in. spaces.

3. 1 @ 15×38-in. jaw crusher, 2 1/2-in. set, 305 r.p.m., 60-hp. motor; operated 50 to 67% of time.

4. 1 @ 16-in.×335-ft. belt conveyor, 200 f.p.m., slight fall; 1 @ 150-ton bin with vibrating feeder.

5. 1 @ 6×6-ft. cylindrical ball mill, 25 r.p.m., 12,000 to 14,000 lb. 5-in. forged-steel balls (1 lb. per ton), manganese-steel liners (life about 6 mo.), 125-hp. motor. Clean-up at relining yields about 200 oz. Au. Trunnion trommel, 24×36-in. with 1/8×1/2-in. slots.

6. 1 @ 4×16-ft. duplex drag classifier; overflow, 17% >48-m.

7. Clark-Todd amalgamator; cleaned biweekly, 2 hr. to change pans.

8. 3-ft. arrastre. Clean-up from (7) is charged with 50 to 70 lb. mercury. Impurities hand skimmed. Soft amalgam squeezed in pillow ticking. Mercury loss about 0.05 oz. per ton of ore.

9. 1 @ 5×5-ft. conditioner, 300 r.p.m., 2-hp. motor.

10. 1 @ 6-cell and 1 @ 4-cell flotation machine in parallel; a = cell 1, b = remainder.

11. 2 Wilfley tables in parallel.

12. 1 half-size Wilfley table; tailing 0.1 oz. Au per ton.

13. 1 @ 4-ft. disk filter; cake, 12% moisture.

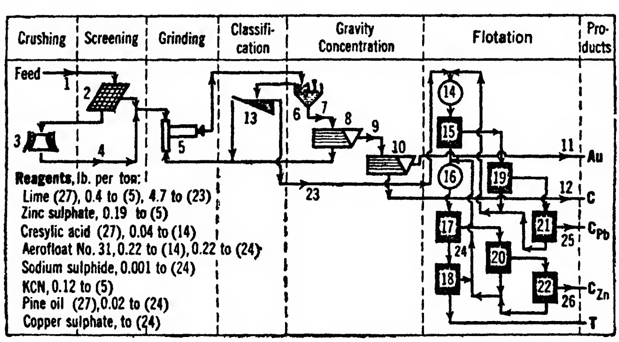
FIG. 76. A. S. & R. Co., ALICE mill.

This flowsheet illustrates relatively inexpensive milling of a low-grade ore at a relatively low daily tonnage, effected by amalgamation, concentration at a surprisingly coarse size, and acceptance of low-grade concentrate and fairly high tailing losses.

Mineral Resources, Inc. Fig. 77 (L. E. Blinzler, Gen'l Sup't, *140 # 11 J 51*).

Location: Santa Cruz, Marinduque, P. I.

Ore: Gold with galena, sphalerite, chalcopyrite, and pyrite in crushed andesite, quartz, and calcite. Ore is abnormally sticky.



Legend for Fig. 77:

1. Horizontal grizzly of 60-lb. rails, 8-in spacing, over 100-ton bin with 2×2-ft. swing-hammer gate; 1 @ 24×50-in. roller-track apron feeder, 28 r.p.m., 2-hp. gear motor; Dings type-20 bipolar high-intensity magnet mounted on a monorail.

2. 1 @ 3×6-ft. Symons 2-deck mechanical vibrating screen, 2-in. openings, 800 s.p.m., 3-hp. V-belt motor.

3. Traylor TY crusher, 9-in. gape, 1 1/4-in. set.

4. 1 @ 16-in.×64-ft. belt conveyor, +18° incline, 200 f.p.m., 2-hp. motor; 125-ton bin with 16-in.×6-ft. belt feeder, adjustable ratchet-and-pawl drive, 9 f.p.m. aver., 2-hp. gear motor.

5. 1 @ 6×6-ft. Marcy ball mill, 25 r.p.m., 125-hp. motor.

6. 1 single-cell Bendelari jig, 160 r.p.m., 3-hp. motor; bed 1 to 1 1/2-in. comprising Nos. 10 and 13C steel shot with coarse sulphide above.

Zinc conc...	0.132	0.605	57.11	2.8
Tailing....	0.0065	0.039	0.260	96.0

Summary. One-stage open-circuit crushing and one-stage closed-circuit grinding from 8-in. to 60-m. Gold is scalped out by a jig in the grinding circuit.

Jig concentrate is twice cleaned on tables and final concentrate amalgamated. Gold-bearing lead and zinc concentrate are made by standard differential methods (Art. 29).

23. SMALL GOLD MILLS

As the term is used here, these are mills with a daily capacity in the range of 25 or less to, say, 75 tons. The flowsheets shown in Fig. 78 are generalized summaries of typical successful installations for the various types of ore listed. Absence of cyanidation in the flowsheets is due to the fact that a cyanide mill requires an investment two to three times that of the mills recommended, and that this differential is not justified for mines in the prospecting and development stages, despite possible higher extractions.

Crushing plant (crushing and screening) comprises a scalping grizzly and a primary crusher and is the same for all of the mills up to 75-ton capacity. Above 75 tons daily such a simple installation may throw an uneconomic burden on the grinding circuit, in which case a secondary crusher is indicated, with or without a scalping screen. At about 150-ton capacity economy in the grinding circuit is likely to require that the secondary-crusher circuit be closed with a screen.

Grinding circuit (grinding plus screening or classification) is one-stage in most mills grinding to normal flotation-feed sizes (48-m. maximum). Hence one grinding mill only is shown in all the flowsheets in Fig. 78. The grinding circuit must be closed in such a way as to insure that an economic percentage of valuable mineral is freed before the pulp escapes from the circuit. Hence a screen is used to close circuit on ores with coarse values and a classifier when the values are medium to fine. This rule is applicable throughout the range of tonnages considered.

Recovery circuits (amalgamation and concentration) are not dependent in flow characteristics on tonnage; this factor determines the size of apparatus only; in small mills where sacrifice of recovery to first cost is justifiable and frequently necessary, the ratio of

[Text continued on p. 127.]

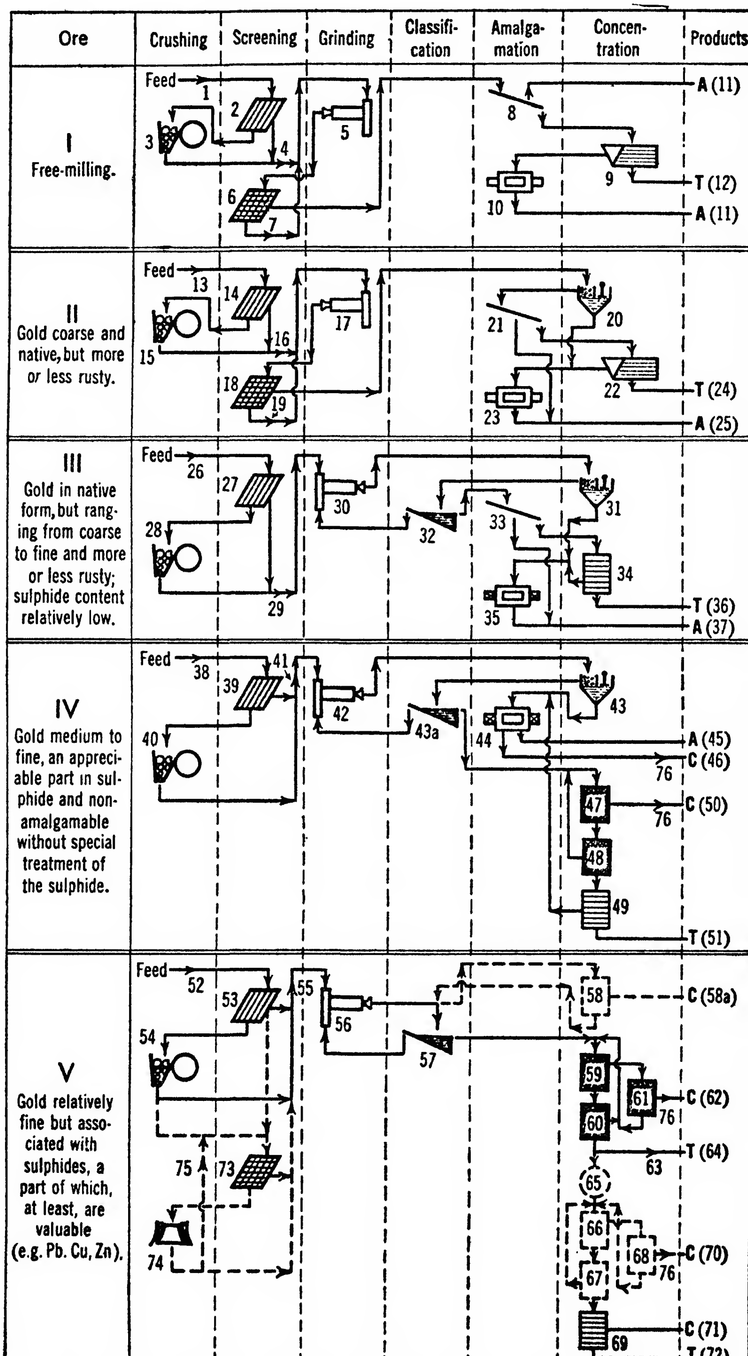

FIG. 78. Generalized flowsheets of small gold mills.

Legend for Fig. 78:

1. Bin or hopper with capacity of several hours' mine run, preferably 24 hr. It should have a grizzly on top to prevent ingress of any lumps larger than can be received by the crusher, and strong enough to withstand sledging. Width of bin gate should be at least three times the aperture of the preceding grizzly, and should operate freely.

2. Bar grizzly forming bottom of chute from bin to crusher, set on a slope such that ore just slides and is, therefore, readily stopped by inserting a shovel, hoe, or the like into the stream. Crusher tender will pick waste here, hence some provision should be made for receiving it and getting it to the waste dump.

3. Crusher with receiving opening large enough to take the great bulk of run-of-mine rock (the balance will be sledged through the bin-top grizzly). This crusher should break to as small a size as is possible at one pass. Maximum reduction ratio is possible in gyratory-type crushers, but capacities and prices are too high for the relatively large receiving openings necessary to take ordinary run-of-mine rock without excessive sledging. A single-toggle type jaw crusher with curved crushing faces and a deep crushing zone will generally serve best in this service.

4. Storage bin with at least 24-hr. capacity. The crusher will normally have enough capacity to break a 24-hr. supply for the mill in a few hours, and provision for change in flow rate should be made here. A laminated bin (see Sec. 18, Art. 3) will probably be cheapest. Some elevation of ore must normally be provided one side or the other of this bin; usually the provision is made on the feed side; a belt conveyor gives less operating trouble than a bucket elevator, but is likely to be more expensive to instal. A belt-type feeder with variable-speed drive is best for discharge of this bin, considering both price and the desirability for control of ball-mill feed rate. Provision should be made on this discharge line for cutting a mill-feed sample.

5. Ball mill. This mill should have the largest standard diameter-length ratio corresponding to the tonnage-size performance demands. If *all* of the gold is coarse, it may be of grate type; normally, however, with the circuit closed by a relatively coarse mesh screen (6), it should be of overflow type so that the mill itself may do a certain amount of selective grinding of the high-gravity gold-bearing particles. Mercury will normally be added to the ball-mill feed box.

6. Screen. This will normally be a trommel bolted to the ball-mill discharge trunnion, but it may be a small trommel or vibrating screen. Either of the latter will probably entail an elevating device for undersize unless the millsite is exceptionally steep. Aperture of this screen should be as small as possible (not more than 1/8-in.); it should not be less than 14-m. unless of the vibrating type, when it may be as small as 48-m.

7. Oversize may be shoveled back to the ball-mill feed box, or some kind of mechanical elevating device (spiral or flight conveyor, bucket elevator, sand wheel, or the like) used. If elevation is required in the undersize line, it may be best to elevate all of the mill discharge to a screen set high enough to return oversize to the mill by gravity. Some trunnion trommels are made with an internal spiral serving to push oversize back through the discharge trunnion, but this practice decreases screen efficiency and returns the oversize to the discharge end of the mill.

8. Amalgamating plate (see Sec. 14, Art. 6). An amalgam trap preceding or following this plate will improve recovery and decrease mercury loss. A blanket table may be substituted for the plate, in which case an amalgam trap is a virtual necessity, if mercury is added to the ball mill.

9. A shaking table (or other gravity concentrator) is placed here both as a safeguard against loss of amalgam and rusty gold and as an indicator of tailing grade.

10. Some form of grinding amalgamator. Usually this will be a revolving barrel with a light load of balls, but it may be of the arrastre or pan type; in either case it will be operated intermittently. There will be a marked hang-back of gold and amalgam in the ball-mill and in any dead pockets in the pulp lines from (5) through to (9). Peculation from such pockets, from the surface of (8), and of concentrate from (9) must be guarded against.

11. Squeezed and retorted, yielding mercury and gold sponge, which is melted (see Sec. 14, Art. 9).

12 This tailing should be sampled and, unless of exceptionally low grade, should be impounded with a view to facilitating further treatment in the future.

13–19. As (1 to 7 respectively) except that mercury is not usually fed to the ball mill.

20. Gravity concentrator to recover coarse nonamalgamable gold. This apparatus may be a riffled sluice, a jig, a shaking table, or a strake. The jig and table have the advantage of continuous operation; the sluice and strake are lower priced and will, in general, save finer gold, but require more attention. The jig causes the least dilution of the pulp returning to the classifier.

21. As (8). The ball mill will ordinarily brighten a certain amount of gold, which may amalgamate here. If, however, the amount so brightened is small, a riffle followed by a strake or strakes alone would be substituted for (20, 21, 22).

22. As (9), but see (21).

23. As (10). With rusty gold some reagent that will dissolve the gold coating is added here.

24. See (12).

25. See (11).

26–29. As (1 to 4 respectively).

30. Ball mill of large diameter-length ratio; it may be of either grate or overflow type. Mercury will normally not be added to the mill feed. See also (5).

31. As (20).

32. A mechanical classifier of the drag, rake, or spiral type; the first is cheapest and least efficient, the spiral is cheaper than the rake; unless extremely fine grinding is necessary the desired re-elevation of sands can probably be attained by any one of the three.

33. As (21) substituting (31, 33, 34) for (20, 21, 22 respectively) in the note.

34. Strake to catch nonamalgamable gold too fine to be caught in (31) under the operating conditions there prevailing.

Legend for Fig. 78—Continued:

35. As (23).
36. As (12).
37. As (11).
38–41. As (1 to 4 respectively).
42. As (30).
43. As (20).
43a. As (32).
44. As (23).
45. As (11).
46. Combine with (50).

47. A subaeration-type flotation machine (Sec. 12, Art. 23) will probably give the best service here, since it possesses maximum operating flexibility and consequent adaptability to the changing conditions inherent in small mill operations. The size of cell and number of cells should be such as to give the necessary time-factor as determined by flotation tests (Sec. 19, Art. 22).

48. This will normally be the later cells of the same machine of which 47 comprises the first cells. The rougher-scavenger flow shown will produce a maximum recovery on a given feed (provided the combined volume of (47) and (48) comprises sufficient volume for the required flotation time) with sufficient enrichment of concentrate from an ore with low sulphide content. If the ore is high in sulphide a much more elaborate flowsheet is necessary (see NORANDA, Fig. 37; MT. LYELL, Fig. 33; OUTOKUMPU, Fig. 34).

49. Strake, to recover gold too fine to be caught in (43) under the conditions prevailing therein and too coarse to be floated. If this concentrate is of such low grade that amalgamation tailing lowers (46) too much, it should be amalgamated separately and the amalgamation tailing sent back to (43a). If amalgamation is not practiced (concentrate from (43) not economically amalgamable), return concentrate from (49) to (43a) or (42), and mix concentrate from (43) with (50) or treat or ship separately according to treatment methods applicable and the economics thereof.

50. Disposal depends upon character of sulphide. Pyrite may be cyanided (custom mill) or smelted. Copper-bearing concentrate should be smelted. Lead-iron concentrate will probably make a maximum yield on smelting, but can be cyanided. Arsenical concentrate may be roasted and the calcine cyanided, or it may be smelted. Choice of method where a choice exists is solely a matter of economics.

51. As (12).
52–55. As (1 to 4 respectively).
56. As (30).
57. As (32).

58. If sulphides free relatively coarse, or if there is some gold present too coarse to float, means should be inserted here to take such material out of the pulp stream. In the absence of coarse gold, this should be a flotation machine (see *Unit cell*, Sec. 12, Art. 23); if coarse gold is to be removed, choose from the apparatus of (20); if both gold and sulphide are available here, both a gravity concentrator and a flotation machine may be desirable, in the order named.

58a. This concentrate will normally be barrel-amalgamated, if the gold content is substantially amenable (see 44, 45, 46). If the ore is lead-bearing, amalgamation tailing will normally join (62); if copper-bearing or arsenical, the probability is that it will be nonamalgamable, in which case see (50).

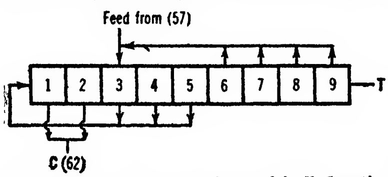

FIG. 79. Arrangement of a multicell flotation machine for rougher-scavenger flow on the primary run, and one cleaning of rough concentrate, with cleaner tailing counterflowed one stage.

59–61. A subaeration-type flotation machine is recommended here for the reason given in (47). One multicell unit will serve for the three stages, with flow arranged after the fashion shown in Fig. 79, in which cells 3 to 5 comprise (59), 6 to 9 are (60), and cells 1, 2 are (61) of Fig. 78. The total number of cells to be used and their size and grouping must be such as to satisfy time requirements (see note 47).

62. See (50).

63. If there is only one valuable sulphide, (69) should be inserted here.

64. As (12).

65–68. These items are to be used when two valuable sulphides are present, *e.g.*, Pb and Zn.

65. A conditioning tank, comprising normally a circular tank with an agitator of sufficient size and power to keep a full charge of pulp in a state of reasonably uniform suspension. The volume of the tank must be great enough to allow time therein for whatever conditioning reaction is necessary (see Sec. 12, Art. 36).

66–68. As (59 to 61).

69. As (49).

70. If zinc concentrate, ship to smelter. In the rare instances where some other kind of concentrate is taken here, disposal is a special problem.

71. Apply the principle of (49).

72. As (12).

73–75. The apparatus and flow lines dotted in here apply when grinding requirements make a finer feed to the grinding unit economically imperative. Normally this condition arises when daily tonnage exceeds 150; it may arise at a lower figure.

73. A vibrating screen of mechanical type is recommended. Screen aperture is that necessary to give ball-mill feed of the desired size, usually 3/8- to 1/2-in. maximum.

74. A secondary crusher of the high-speed gyratory type (see Sec. 4, Arts. 6 and 7). Size depends upon the duty demanded.

75. Whether or not the secondary-crusher circuit is closed on screen (73) depends upon the rigor of the requirement as to ball-mill feed size; if a small amount of oversize in this feed can be tolerated, (74) is run open-circuit, otherwise an elevating device (see discussion in note 4) must be provided and the circuit closed. Such closure increases the tonnage fed to (73) and (74) (see Sec. 19, Art. 24), and this fact must be allowed for.

76. In small mills fine concentrate is usually run directly to a filter, or better to a surge tank or sump from which it can be drawn to the filter as desired; larger mills place a thickener ahead of the filter. A disk-type vacuum filter is recommended for small mill service.

daily tonnage to machine unit size is normally much larger than in the large mill. For mills of 100-ton capacity upward, with any reasonable assurance of continued ore supply, the possibilities of cyanidation should be investigated.

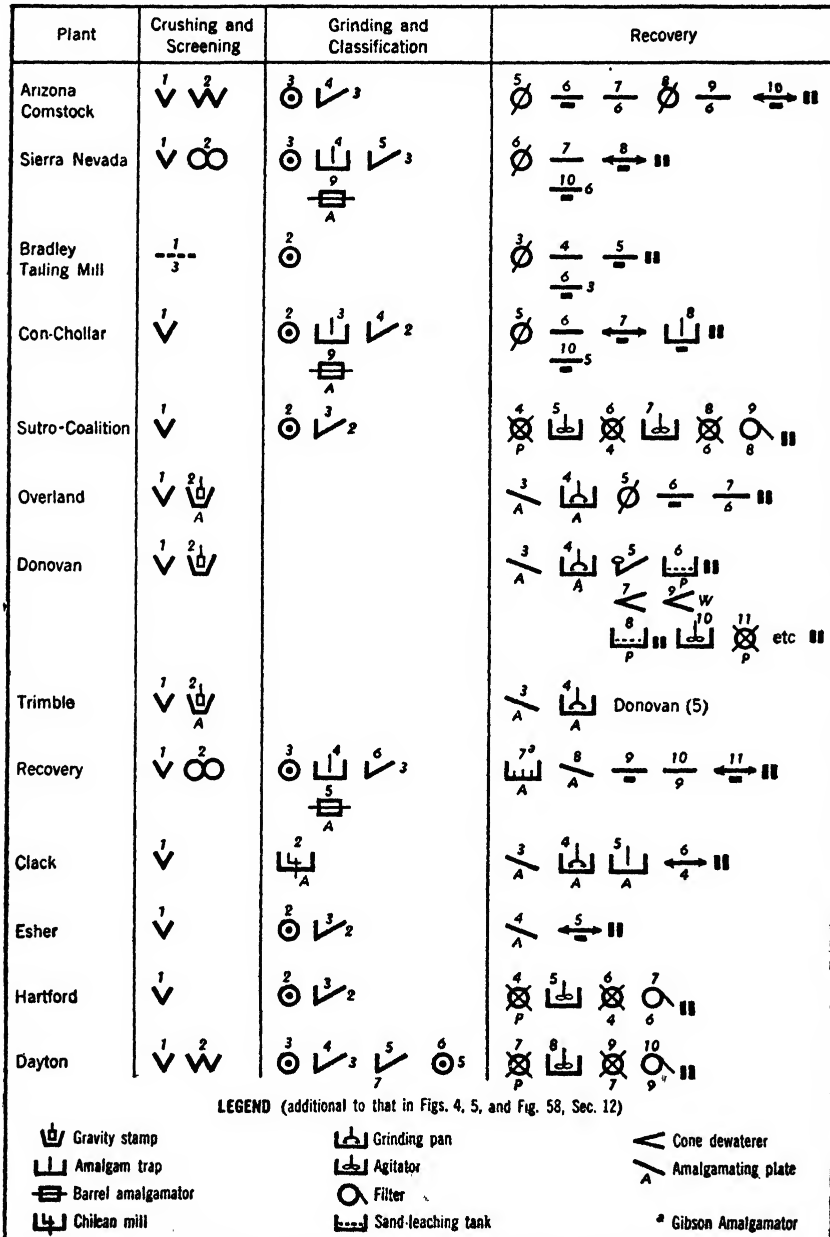

FIG. 80. Flowsheets of Comstock gold mills.

Costs (1937) of all-new equipment for Type I mills of 5- and of 50-ton daily capacity was $300 and $120 per ton of daily capacity respectively, with intermediate prices varying

linearly according to tonnage; corresponding figures for Type II mills were $440 and $145, Type III, $500 and $170; Type IV, $700 and $230; and Type V, without items 63 to 68 and 73 to 75, $750 to $250. Ziegler (*23 #10 MCJ 38*) sets the costs of small (<200 t.p.d.) single-product flotation plants, excluding power and extensive water supply, at $300 to $600 per daily ton, the higher figure for low tonnages; for two-product flotation, add 30%; cyanidation may reach $1,000 per daily ton, if all-sliming and vacuum precipitation are provided for. For installation and housing costs, and for mills in the upper part of the range discussed, see Sec. 20.

Water requirements for mills of Types I, II, and III are about 4 to 5 tons per ton of mill feed and for Types IV and V from 3 to 4 tons, without reclamation.

Power installation required will range from 1 to 2 hp. per ton for Types I and II up to 3 hp. maximum (corresponding to a small-tonnage mill) for Type V.

Fig. 80 gives skeleton flowsheets of 12 mills treating low-grade (0.08- to 0.15-oz.) gold ores near Virginia City, Nev., discussed by Gardner and Carpenter (*San Francisco Meeting AIME, Oct., 1935*). The mills are straight amalgamation; amalgamation plus flotation; gravity concentration and flotation, shipping concentrate; and straight cyanidation. All but Arizona Comstock (330 t.p.d.) treat 100 tons per day or less. The amalgamation and the concentration plants make 60 to 75% recoveries; cyanidation makes upward of 90%. Costs range from $1 to $2 per ton milled. Variations in flowsheet are said to be justified by the various operators on the score that ores differ or that the other fellow is wrong.

Clean-up of old gold mills is an unfailing source of considerable recovery. The principal locations of gold are (*38 JCM 441*): made ground, rubbish dumps, smelting-ash dumps; sumps, drains and floors in the mill; wooden tables, launders, etc., in the mill; scale throughout the plant, particularly in pipes and classifiers; amalgam plates, chips from the grinding plant, extractor boxes, vats and sumps in the cyanide plant; and all dust, brick, and wood from the refinery house. Treatment is to burn all organic matter, then crush, and concentrate by gravity, finishing over a strake.

24. SILVER

Uses. The principal use is as a component of an alloy for coins, jewelry, and tableware. The chief alloys are those with aluminum, copper, zinc, nickel, and combinations of the same. Salts of silver are used to some extent in medicine and to a great extent in photography.

Ores. The economic minerals are metallic silver, argentite, argentiferous galena, cerargyrite, proustite, pyrargyrite, stephanite, tetrahedrite, polybasite. The most important ores are the silver-bearing lead ores in which the heavy mineral is principally argentiferous galena, usually associated with pyrite, sphalerite and rich silver-bearing minerals. The usual gangue minerals are quartz, calcite, barite, and chert. The copper ores of Col-

a Preliminary estimate. *b* Includes Philippines. *c* Includes Burma.

orado, Utah, Montana, and Arizona produce considerable silver. Silver is also usually associated with gold in both quartz-vein and placer types of deposit. Native silver and sulphides in quartz associated with a complex mixture of sulphides, arsenides, antimonides, etc., were important at Cobalt, Ont.

Production. World production is a fairly constant quantity, ranging, since 1893, between 161,000,000 and 274,000,000 troy ounces. Distribution of production is shown in Table 55.

Selling. See Art. 50. Price of silver is a political football; past prices are no guide to the future.

Sunshine Mining Co. Fig. 81 (*Q* by W. Church Holmes, Mill Sup't and Metallurgist).

Location: Kellogg, Idaho.

Ore: Argentiferous tetrahedrite with pyrite and small amounts of galena, stibnite, and arsenopyrite in siderite and quartz.

Capacity: Ranges from 750 to 1,200 tons per 24 hr.

Assays: Feed, oz. Ag per ton: 48.2 (1937), 36.2 (1938); concentrate: maintained as near 1,000 oz. per ton as possible by variable rejection of a finely intergrown pyrite middling; averages for 1937 and 1938 follow:

	Au, oz.	Ag, oz.	Cu, %	Pb, %	As, %	Sb, %	S, %	Fe, %	Insol., %
1937	0.03	1010.0	12.57	4.99	1.65	10.22	34.4	24.7	3.4
1938	0.032	983.8	12.30	3.06	2.03	9.89	35.4	26.0	3.5

Tailing: ranges according to pyrite rejection as above from 0.7 to 0.95 oz. Ag per ton; average for 1937 was 0.86 oz.; for 1938, 0.94 oz.; for first quarter 1939, 0.77 oz.

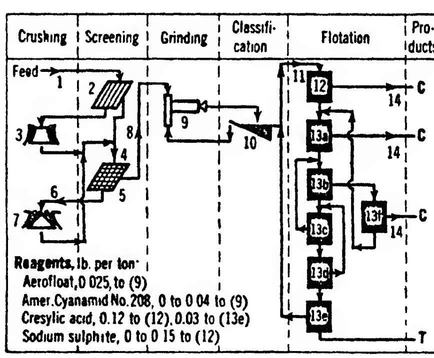
Recovery: 98.3% Ag (1937); 97.5% (1938).

Ratio of concentration: 21.3 : 1 (1937); 27.9 : 1 (1938).

Water: Comes by gravity through 14-in. wood-stave pipe 1 mi. from dam; CONSUMPTION 2.75 tons per ton milled, none reclaimed.

Power: Purchased at 2,300 volts; motors, 2,300- and 440-volt; CONSUMPTION, 19.4 hp-hr. per ton milled.

Labor: American. 85 tons per man-shift, operating; 350 tons per man-shift, repairs.



Legend for Fig. 81:

1. 1 @ 650-ton bin; Link-Belt apron feeder; 1 @ 30-in. belt conveyor with magnetic head pulley.

2. Cantilever grizzly.

3. 1 @ 3-ft. Traylor TZ reduction gyratory.

4. 1 @ 24-in. belt conveyor; 1 surge bin.

13. 2 @ 20-cell 24-in. Denver Sub-A flotation machines; *a* = cell 2, *b* = cells 3 to 5, *c* = cells 6 to 8, *d* = cells 9 to 12, *e* = cells 13 to 20, *f* = cell 1. 295 and 300 r.p.m.; rubber-covered impeller and hood last 4 yr. Feed, 28% solids, *p*H 7.8; time-factor, 20 min.

14. Combined concentrate filtered, sent to 80-ton bin, and transported by truck and railroad to smelter.

FIG. 81. SUNSHINE MINING CO.

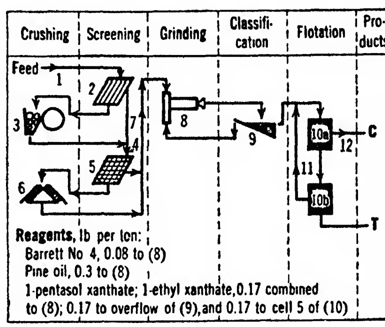
Mill building: Sloping site. Steel and wood frame, galvanized-iron enclosure. Concrete for base floors and 2×4-in. slats on edge and spaced for intermediate floors; slope concrete in wet part, 1/4 in. per ft. Heated. 15-ton hand-operated traveling crane in coarse-crushing section; single-track traveling power hoist in grinding section.

Transportation: Mill at mine. Concentrate shipped 2 mi. by truck to railroad and thence 6 mi. to smelter; 8.3% moisture.

Tailing disposal: 2 mi. by gravity through 12-in. wood-stave pipe to river; in conjunction with other operators in district a suction dredge is maintained about 20 mi. down river, which removes and impounds joint tailing.

Veta Mines, Inc., Ash Peak mine. Fig. 82 (*IC 7119; Tref 1/41*).

Location: Duncan, Ariz.
Ore: Argentite associated with pyrite, calcite, and rhodochrosite in quartz and silicified andesite.
Capacity: 190 tons per 24 hr.
Assays: Feed, 11 oz. Ag and 0.025 oz. Au pe ton; concentrate, 550 oz. Ag and 1.5 oz. Au with about 1% combined Pb, Cu, Zn, and 6% Fe.
Recovery: Ag, 65%.
Ratio of concentration: 110 : 1.
Water from a well pumped 7,000 ft. through a lift of 1,400 ft. CONSUMPTION, 5.7 tons new water per ton of ore; cost, $0.09 per ton milled.
Power: Company-generated by Diesel engines; motors, 2,300-volt (crusher and ball-mill), 440-volt for all others down to 1-hp.
Labor: 24 tons per man-shift, operating.
Millsite steeply sloping; building is wood-frame with corrugated-iron cover.
Transportation: Mine at mill. Concentrate (18% moisture) is trucked in 225-lb. sacks 215 mi. to El Paso at a cost of $6 per ton.
Costs: Crushing, $0.17 per ton; milling, 0.81; concentrate handling, 0.09; total operating, $1.07.



Legend for Fig. 82:

1. R.o.m. <10-in. grizzly to 65-ton storage.
2. Grizzly, 2-in. spacing.
3. 1 @ 12×16-in. Buchanan jaw crusher, 2-in. open setting, 25-hp. motor. Manganese-steel jaw plates must be changed weekly; they are built up by hard-facing.
4. 1 @ 18-in.×40-ft. belt conveyor, +20°, 150 f.p.m., with magnetic head pulley.
5. 1 @ 30×48-in. vibrating screen, 1/4-in. aperture, 2-hp. motor.
6. 1 @ 3-ft. short-head cone crusher, 3/4-in. set, 60-hp. motor.
7. 1 @ 16-in.×20-ft. belt conveyor; 1 @ 16-in.× 175-ft. conveyor, +17°; 1 @ 16-in.×20-ft. distributing conveyor; 2 @ 200-ton bins; 1 @ 20-in.×35-ft. flat feeder belt.
8. 1 @ 6×10-ft. overflow-type ball mill, manganese-steel liners (0.7 lb. per ton), 30,000 lb. @ 3-in. forged-steel balls (4.2 lb. per ton; consumption of cast-iron balls was about twice this), 24 r.p.m., 200-hp. motor, 72% solids.
9. 1 @ 6×24-ft. duplex rake classifier. Circulating load about 800%. Overflow 4% >100-m., 68% <200-m., 18 to 19% solids. Chips from screen on classifier overflow yield ash carrying 80 oz. Ag and 0.5 oz. Au per ton of ash.
10. 1 @ 10-cell 21-in. M-S type subaeration cell; *a* = cells 1 to 3, *b* = remaining cells.
11. 1 @ 1-in. Wilfley pump.
12. 1 @ 12×8-ft. thickener, copper sulphate, 0.03 lb. per ton of original feed, added as a settling agent, overflow contains 2 to 3% solids, underflow 50% solids. 1 @ 4×2-ft. drum filter; bin; sacks; truck; smelter. Thickener overflow goes to 2 settling tanks in series; settlings are removed and sacked at intervals.

FIG. 82. VETA MINES

Summary. Two-stage crushing and one-stage grinding to 65 *mog*. Flotation concentration by simple rougher-scavenger routing. Higher flotation recoveries could be made by finer grinding and up to 80% recovery by cyanidation of crude ore or tailing, but not profitably.

25. CUSTOM MILLS

These are mills adapted to the treatment of a variety of ores which have in common only, usually, the fact that they contain enough precious metal to pay for ore haulage, sampling, and milling at rates sufficiently higher than those prevailing at well run owner-operated plants to pay the middlemen profits. They are often run in connection with smelters (*e.g.*, MIDVALE, Fig. 124; TOOELE, Fig. 127), but may serve and be placed in or near a mining district of considerable area and production tonnage removed from a smelter (GOLDEN CYCLE, Fig. 83; EAGLE-PICHER CENTRAL, Fig. 117) or may simply be a small mill in a small district (RECOVERY, Fig. 80). For usual settlement methods see Art. 50. The essential elements of a good custom mill are: (*a*) an accurate sampling plant sufficiently open to permit clear observation of the flow, and with suitable provision to prevent dust loss; (*b*) adequate storage facilities for segregation of small lots at reasonable expense; (*c*) adequate provision for mixing lots to a composition not too far from some standard; (*d*) a flexible pulp-transport system to permit ready variation of treatment according to the ore; (*e*) a variety of efficient treatment schemes.

Golden Cycle Corp. Fig. 83 (*136 J 381; IC 6739*).

Location: Colorado Springs, Colo.

Ore: Sulphotelluride gold ores with small amounts of silver and negligible amounts of base metals; copper ores; and complex lead-zinc ores, mostly gold bearing. Assay of feed averages 0.30 to 0.37 oz. Au per ton.

Capacity: 1,500 t.p.d.

Recovery: Tailing <0.5% Pb; <0.1% Cu; 0.02 oz. Au, $0.024 soluble. Aim is to keep as much gold as possible in the plant and ship as much lead, copper, and silver as possible to the smelter. Total recovery of gold about 95%.

Cost (1935): $1.50 per ton, operating only, of which sampling is a considerable part. Cost of cyaniding flotation tailing estimated at 15 to 20¢ per ton.

13. To assay office. See Sec. 19, Art. 7.
14. Compartmented hot-storage bins.
15. Belt conveyor with Dings magnetic head pulley.
16. Stationary screen, 5/8-in. sq. openings.
17. 1 @ 5 1/2-ft. short-head cone crusher, set 1/8- to 3/16-in.
18. 4 Hum-mer screens, 4-m. aperture.
19. 1 as (13), for concentrating ores.
20. 2 @ 6×6-ft. Schmidt Kominuters in parallel, for roaster ores.
21. Roaster-ore storage and mixing bins.
22. Concentrating-ore storage and mixing bins.
23. 3 @ 6×6-ft. grate-type ball mills, 23 and 24 r.p.m., low ball load, 2 1/2- and 3-in. cast balls, 1.7 lb. per ton. Feed to 3 mills, 444 t.p.d.
23*a*. When used for complex ore, grind is finer and feed rate 400 t.p.d.
24. Elevator.
25. 3 @ 4×4-ft. trommels, 6-m. cloth.
25*a*. Not used with gold-silver noncomplex ores; ball-mill discharge goes direct to classifier (29*a*).
26. 2 @ No. 500 Denver unit cells.
26*a*. By-passed with noncomplex gold-silver ores; see (25*a*).
27. 5 Wilfley tables.
28. Elevator.
29. 1 @ 6×23 1/3-ft. duplex rake classifier, 2 1/2-in. slope, 22 s.p.m.; overflow 1.2% >35-m., 43.6% <200-m.
29*a*. Same classifier as (29) but 17 r.p.m.; overflow 1.9% >65-m., 63.5% <200-m.
30. 2 @ No. 18 Spl. Denver Sub-A machines in parallel.
31. 1 @ 2×28-ft. Stearns-Rogers drag dewaterer.
32. Agitator alternative.
33. 1 @ 17×6-ft. thickener.
34. 1 @ 6-ft. 5-disk American filter.
35. Storage bin for pyrite-gold concentrator.
36. Barren cyanide solution used to wash concentrate down launders; contains enough lime and cyanide to effect partial solution of gold and silver.
37. 1 @ 50×7-ft. thickener. A minimum of lime to give clear overflow added here; quantity must be kept down, or trouble follows in flotation. Excess is counteracted by soda ash in flotation, but excess of soda ash causes dispersion in (37) and requires more lime; care is necessary to maintain balance. Maximum of 0.05 CaO is sought, and *p*H is held to 7.2 to 7.6 in lead-copper flotation.
38. 2 @ 10×8-ft. Denver conditioners in parallel.
39. 2 @ No. 18 Spl. Denver Sub-A machines in parallel. Operated to make as small a concentrate as is consistent with flotation of all Pb and Cu and as much Ag as possible.
40. 2-in. Wilfley pump.
41. 1 @ 16×6-ft. thickener.
42. Solution to cyanide plant.
43. 1-in. Wilfley pump.
44. 1 @ 6-ft. 6-disk American filter.
45. Storage-drying bins with steam coils in bottom.
46. Shipped to smelter at Leadville. May be a straight copper concentrate with some ores.
47. 1 @ 4-cell 24-in. Denver Sub-A flotation machine.
48. 6 Wilfley tables.
49. Contains gold from cyanide added to (38) to depress Fe and Zn (see Sec. 12, Art. 10). Kept in the flotation circuit until several days after addition of cyanide to circuit has ceased (operation on flow for simple gold ores), when gold content will have dropped sufficiently to permit discharge to the main mill-water circuit.
50. Both overflow and cone concentrates.
51. To (29*a*) when feed is from (26*a*).
52. 8 @ 13×115-ft. Edwards duplex roasting furnaces each with 1 @ 13×44-ft. cooling hearth; slope, 1 in. per ft.; 74 rabbles, 54 in roaster, 3 r.p.m. in roaster, 6 in cooler, 16 hp. consumed each unit, 5 to 6 hr. time-factor, 170 to 180 lb. lignite per ton. Cooled to 85° C.
53. 6 @ 6-ft. Chilean mills.
54. 6 @ 6×12-ft. strakes with light-weight Canton-flannel cover, changed every 12 hr. and washed by sprays and in a barrel washing machine. Recovery is 22 to 40% of total recovered gold.
55. Wheeler grinding pans; mercury added as well as regular mill cyanide solution.
56. Retort.
57. Melting crucible.
58. 920 to 940 fine; 45 to 55 fine in Ag.
59. 15(diam.)-ft. bowl-rake classifier. Overflow, 7% solids.
60. 10 @ 50(diam.)×10 3/4-ft. vats, 900-ton (dry-sand) capacity ea. Water at 120-lb pressure used for flushing.
61. 1 @ 50-ft. tray thickener; spigot product 43% solids; 4 to 5% >100-m., 84% <200-m. Overflow circulated until cool in order to cause sulphates to be dropped before reaching press (74).
62. 1 @ 41×26-ft. Dorr agitator.
63. 1 @ 37×24 3/4- and 1 @ 35 2/3×17-ft. Dorr agitator in parallel.

65. 1 @ 30 1/2×14-ft. Dorr agitator.
66. 3 @ 30 5/6×10 1/4-ft. tray thickeners in parallel; spigots to 1 @ 30 5/6×10 1/4-ft. Hardinge Superthickener.
67. 1 @ 3-in. centrifugal pump.
68. 1 @ 37×24 3/4-ft. Dorr agitator. Total time of agitation, (58) through (64), is 65 to 75 hr.
69. 2 @ 30 2/3×10 1/4-ft. mechanically agitated surge tanks (filled alternately).
70. 2 Butters filters, 121 @ 6 1/2×9 1/2-ft canvas-covered frames.
71. 1 @ 30×9-ft. solution-storage tank.
72. Crowe vacuum system.
73. Centrifugal pump.
74. 6 Merrill precipitation presses.
75. Coal-fired muffle.
76. Rockwell furnace.
77. Graphite crucible.

Summary. Concentration to prepare suitable feed for roasting and cyanidation. Concentration reduces the tonnage of roaster feed (*e.g.*, only 3 to 5% of the low-grade telluride ore goes through the roaster), removes the cyanicides from complex ores, and removes coarse gold. Concentration also removes soluble salts by washing and precipitation with lime. High flexibility is gained by multiple branching of pulp lines.

See also Sec. 19, Art. 6.

26. INDIUM

Uses. Dental amalgams and alloys. Low-melting alloys; Wood's metal plus 18% In is fluid at 46.5° C. Alloyed with or plated on silver to prevent tarnish. Polished In has high reflecting power. In a glass containing sulphur compounds, 0.05% In_2O_3 imparts a fine yellow color, darker with larger proportions. Indium (0.2%) added to Cd-Ag, Cd-Ni, or Cd-Ag-Cu bearing alloys greatly improves their resistance to the corrosion caused by acidity that develops under oxidation in some lubricating oils (*128 A 295*). A more practicable method is to deposit a thin plating of indium, electrolytically, on the bearing surface of such an alloy, and then cause the plating to diffuse by heating at 340° F.; indium will thus penetrate to depth of 0.010 to 0.015 in. in 2 hr., and, if present to an amount of 0.4 to 0.5% of the metal to that depth, will completely counteract the most serious corrosion conditions, without causing embrittlement.

Ores. Indium is almost invariably associated with gallium (less consistently with germanium) in sulphide and oxidized ores of zinc; some Western blende concentrates are estimated to contain up to 15 oz. In per ton. It occurs also in iron, manganese, and tin ores. The metal becomes concentrated in the dross of zinc redistillation retorts (*cf.* gallium, Art. 17) and in the residues from purification of $ZnSO_4$ electrolyte, particularly in the cadmium, etc., precipitated upon zinc; lithopone manufacturers employ a similar method of purification.

Prices. In March, 1939, quotations were reduced from $90 per oz. (av.) to $28.35 for 99% and $56.70 for 99.9% metal. The Belgochemie in Belgium, Furnkawa in Japan, and the American Smelting & Refining Co. were reported as producers.

Treatment. Indium is segregated from other constituents of the above-mentioned cadmium mud by repeated and alternated solution in H_2SO_4 and reprecipitation on the purest obtainable zinc; In is the least rapidly soluble of the several metals involved. From the final solution of $In_2(SO_4)_3$, a *large excess* of NH_4OH precipitates $In_2(OH)_3$ while any Zn, Cd, Ni, or Cu remains in solution. Ignition of the washed precipitate (at 600° to 700° C.) yields In_2O_3 about 99.5% pure, which can be reduced electrolytically to metal of 97 to 98.5% grade. The most satisfactory electrolyte is prepared as follows: Dissolve (in proportion of) 200 gm. In_2O_3 in 600 cc. water and 120 cc. of 96% H_2SO_4; add 250 gm. sodium citrate crystals and dilute to 1,000 cc. Electrolyze at ordinary temperature with platinum anode and sheet-steel cathode, at cathode current density of 2 amp. per sq. dcm. Compact deposits up to 1/2-in. thickness are obtained. Electrolyte may be completely denuded, or it may be replenished with wet $In_2(OH)_3$ filter cake; dry or ignited hydroxide is not readily soluble in depleted bath. Cathodes are stripped by heating to 180° C. in an oven (*57 AES 289; 30 IEC 611*).

27. IRIDIUM

Uses. Chiefly as a hardening alloy for platinum; jeweller's platinum usually contains about 10% Ir; alloys with up to 50% Ir are found in certain electrical instruments where brittleness is not objectionable. Other uses for Pt-Ir alloys: pen points, standardized weights, surgical instruments, and needles.

Occurrence. Almost invariably combined (together with other metals of the platinum group) in crude platinum, averaging 1 to 2% Ir in the most productive platinum localities. Alluvial platinum from the Goodnews Bay district, Alaska, is exceptionally rich in iridium, ranging from 5.9 to 22% of the product (*Bul 910-B USGS*). Iridium occurs also in a natural alloy of which osmium is the principal other component (osmiridium, Art. 35). Iridium rarely occurs with the platinum derived from copper-nickel ores.

Production and consumption. Recovery of iridium by U. S. refiners was 1,051 troy oz. in 1939 (having fallen from 2,438 oz. in 1935); in late years 75 to 80% of the output has been recovered from imported crude platinum. Of the total domestic consumption of iridium (4,322 oz. in 1939) about 70% was utilized in jewelry, 21% in electrical devices, remainder for dental and chemical uses.

Prices. Iridium was quoted at $112.67 per troy oz. in 1939, an advance of 62% over the 1938 price, and a much greater increase than occurred with platinum or palladium.

Treatment. For technical methods of separating and recovering Ir from the other platinum metals, see *76 A 602;* for recovery from jeweller's waste, *see TP 342 USBM;* see also *Liddell.*

.28. IRON

Uses of iron are multitudinous; it is used almost entirely as cast iron or steel, both of which are alloys or mixtures of iron with carbon and other elements such as phosphorus, manganese, chromium, nickel, tungsten, vanadium, molybdenum, cobalt, silicon, titanium.

Ores. The economic minerals are hematite, magnetite, goethite, limonite, siderite, and very occasionally pyrite. For a deposit of one of the above minerals to constitute an ore it must be favorably located with respect to fluxes, fuel, and markets; it must be of high grade; must occur in large quantity; and must lie so that mining will be possible on a large scale at comparatively low cost. Furthermore, it should be relatively free of titanium, phosphorus, and (excepting the pyrite which will require oxidation and leaching) of sulphur, which are harmful in the finished iron and steel products and difficult or impossible to eliminate. Analyses of typical domestic ores are shown in Table 56.

Table 56. Average composition of typical iron ores

Content	Ore

a Appalachians from N. Y. to Ala. *b* Ala., Pa., Texas, Iowa.

Most of the iron ore now mined and that mined in the past have been of sufficiently high grade to smelt without concentration, but the end of the known high-grade deposits, located close enough to fuel and to consumption centers to make them presently profitable, is in sight, and an increasing proportion of lower-grade ores is concentrated every year.

Classification of ores (U. S.). No standard official classification exists, but most operators use an approximation of the following terminology:

Merchantable ore assays between 50 and 60% Fe and is smeltable without further enrichment. (See also *Alabama iron ores.*) Limitations as to maximum size and as to percentage of <65-m. may be imposed. Certain near-merchantable ore comprises soft iron mineral admixed with coarse hard siliceous gangue which is readily separated by screening, with or without supplemental hand picking, thus raising the ore to merchantable grade. Certain other ores of near-merchantable grade contain water, either physically held or chemically bound or both, in such quantities that when it is removed by heating the residue is merchantable.

Concentrating ore comprises rock assaying normally from 40 to 50% Fe from which a concentrate of approximately merchantable-ore character can be made, or from which a concentrate can be made that, when mixed with a high-grade merchantable ore, will form a merchantable mixture. Concentrating ores in which the iron minerals are hematite or hydrated oxides are further classified as wash ores and low-grade concentrating ores.

Wash ores. The typical wash ore occurs as alternating bands of high-grade iron oxide and lightly consolidated sand which is predominantly <80-m. After mining, these bands constitute a mixture of lump iron mineral sufficiently hard to resist serious breakage and abrasion when subjected to movement and tumbling such as is incurred in passage through a rotary screen or log washer, and fine relatively iron-free sand. (See Table 57.)

Low-grade concentrating ores are differentiated from wash ores in that the gangue is locked with the ore minerals to the extent that crushing is required to sever the two; they are normally further distinguished by the much coarser size of the gangue aggregates.

Magnetic ores are the ores of magnetite. They may be merchantable as mined, but usually require concentration. They never have the characteristics of wash ores. Estimated reserves (1939) in the Eastern U. S. are 600 million tons of 40 to 60% iron content in New Jersey, 900 million tons of the

same grade in east-northern New York, and 70 to 80 million tons in eastern Pennsylvania. The eastern Mesabi magnetites are of lower grade, but of enormous tonnage.

Nonconcentratable rock simply means iron-bearing rock which cannot be made to yield merchantable concentrate at a profit at present prices with presently known methods of concentration. In the Lake Superior district it embraces both low-grade (20 to 30% Fe) coarse-grained rock and medium to relatively high grade rock (35 to 45% Fe) of such fine texture that fine grinding is necessary to sever the gangue. Concentration is readily effected with both types of rock, but the first has too high a ratio of concentration while the second requires too costly treatment. Known reserves of this rock in the Lake Superior district alone are estimated to amount to 57 billion tons (*22 #12 MCJ 20*), much of it readily minable, and cheaper combinations of concentration and smelting may be expected when the deadening competition of merchantable and high-grade concentrating ores disappears. Not the least of the present deterrents to work on this material is the confiscatory tax system now in effect.

Table 57. Sizing-assay test of typical wash ore (*RI 3052*)

Size	Per cent. weight	Per cent. iron
>1.050-in.	7.65	59.36
0.742	6.73	59.36
0.371	17.12	58.71
4-m.	15.63	59.26
8	9.39	58.80
14	5.76	57.33
28	3.85	55.21
48	2.97	52.44
65	1.40	48.57
100	1.40	41.57
<100	28.10	13.46
Unsized	100.00	45.30

Bessemer and non-Bessemer ores. The Bessemer process of steel making concentrates phosphorus in the steel. Hence shipping product containing more than 0.045% phosphorus is classed as NON-BESSEMER, and concentrating ore which yields such concentrate is likewise non-Bessemer. BESSEMER ORE is ore or concentrate containing less than 0.045% phosphorus.

Manganiferous iron ores are found on the Cuyuna range in Minnesota. The most abundant are the BROWN ORES, which are low in manganese (<10%) and low in silica but high in phosphorus; the BLACK ORES comprise a very intimate mixture of manganite, hematite, and ferruginous chert in which the manganese, which tends to predominate in the coarser sizes, may run as high as 25 to 30% in comparison to a 20 to 30% iron content. Phosphorus is lower than in the brown ore but silica is higher. The black ores as mined usually contain a large amount (up to 30%) of water, both free and combined, and hence are capable of considerable concentration by drying and sintering.

Objectionable impurities in iron ore are those which cannot be removed by concentration and which, if sent to the blast-furnace, carry through the pig iron into the steel in amounts which harm the properties of the steel. The principal impurities in this class are sulphur and phosphorus. Allowable limits are discussed in Art. 50. Silicon is objectionable because it must be slagged off, with attendant proportionate consumption of limestone and coke, which additionally occupy furnace space and thereby reduce furnace capacity and increase labor cost. Titanium requires very high temperatures for reduction; unreduced it thickens slag mechanically.

For production of metal from ores and concentrates see: *Ferrous Production Metallurgy*, J. L. Bray, John Wiley & Sons, Inc. (1942); *Blast Furnace Practice*, R. H. Sweetser, McGraw-Hill Book Co. (1938); *Blast Furnace Practice*, Fred Clements, Ernest Benn, Ltd. (London, 1929).

Production of iron ore in the United States, by states, is given in Table 58. Exports of iron and steel are three to four times greater than imports. World production of pig iron is given in Table 59.

Selling. See Art. 50.

Lake Superior base prices f.o.b. Lake Erie docks for Old Range Bessemer ore have ranged from $4.75 to $5.25 per long ton over the period 1929–1943; Old Range non-Bessemer and Mesabi Bessemer bases have been 15¢ off these prices, and Mesabi non-Bessemer 30¢ off.

Treatment. Iron is the second most widely distributed metal and constitutes the fourth largest elementary component of the earth's crust. The iron content of most rocks is higher than that of the valuable-metal content of the ores of most other metals. But workable iron ores are relatively limited in distribution because iron is a low-priced commodity and consequently must be present in high natural concentration in a rock in order that the cost of mining, beneficiation, and reduction per unit of iron content may bring production cost below the market price of the metal.

The primary product from iron ore is pig iron, produced by smelting in a blast furnace. Hence the requirements for economic blast-furnace operation set the specifications for iron-ore shipments. These requirements differ in different parts of the world. The furnaces which treat the ores from the Lake Superior mines are located at the lower Great Lakes ports and south therefrom as far as Pittsburg; their schedule for merchantable ore is based on a minimum assay of 51.5% natural iron and a SiO_2 maximum of about 10 to 12%. In the Birmingham district, because of the self-fluxing nature of the ore, lower iron and somewhat higher silica contents are acceptable. Eastern and foreign furnaces have yet different standard requirements.

The desideratum in iron-ore treatment is maximum weight recovery with iron content in concentrate above a guaranteed minimum and size within specified maximum and minimum limits.

Crushing plants are those in which merchantable ore too coarse for ready passage around the blast-furnace bell are crushed to a maximum size ranging from 8-in. to, say, 3-in., according to the blast-furnace feed arrangements. The crushing is normally one-stage jaw crushing, but conceivably two stages with intermediate scalping would be necessary, if large lumps of hard ore needed crushing to 3-in. maximum. Crushing is the most widely used form of iron-ore dressing.

Drying plants and sintering plants. Cuyuna range ores may contain as high as 30% water as mined; fine concentrate will normally contain from 10 to 40% moisture, according to size and the method of dewatering. Marked changes in iron content on an as-shipped basis can, therefore, be made by drying, with an incidental saving in freight. Simple drying will not, in general, drive off combined water; it has also the disadvantage of increasing dusting in handling and furnacing. Sintering drives off combined water, agglomerates fines into porous lumps, and improves the furnace behavior markedly. Drying is usually done in direct-heat rotary driers (Sec. 17, Art. 3). For sintering practice see *Bray; Sweetser*. The heat in the discharge from the sintering machines is utilized to dry lump ore by dumping the two together into the steel gondola cars in which they are shipped from the mill.

Screening plant. The simplest form of concentration is typified by the early plant at the SUSQUEHANNA mine at Hibbing, Minn. (*102 J 787*), where masses of taconite occurred

scattered through the hematite. In the earliest operations the taconite was picked out ahead of the steam shovels and hauled away in dump cars. This expensive operation was replaced by screening.

The ore was loaded by steam shovel into 12-cyd. air-operated side-dump cars, taken to the screening plant and dumped onto a flat grizzly with 30-in. spacing. Oversize was sledged through into a bin. From the bin the ore was drawn into a 5×24-ft. revolving stone screen with 2-in. round holes. Oversize was waste, which discharged into a car-loading bin, whence it was hauled to a rock dump. Undersize went to the shipping bins. Capacity of this plant was about 250 t.p.h. and it required only about 30 hp.

Washing plants utilize tumbling in water to disintegrate lightly clay-bound sand and to abrade adhering sand from lump hematite, and sizing by classification and/or by screens to separate the resulting mixture of relatively coarser hematite and fine sand and clay. Such plants are typified by some twenty-odd mills in the western Mesabi district. Upward of 80% of all Minnesota iron concentrate is obtained by washing.

The older practice (see Fig. 83, *Ed. 1*, p. 140) was to hand-pick waste from >2-in. material, the residue being concentrate; log-wash <2-in. size, taking the washed product as concentrate; rewash the overflow in turbo washers, again taking the washed product as concentrate; desliming turbo-washer overflow in settling tanks, discarding slime, and concentrating the granular settlings on shaking tables.

Modern Mesabi practice is represented by the flowsheet of the Canisteo plant (Fig. 84) in which the second stage of log washing and the tabling have been replaced by a bowl-rake classifier, and in which provision is made for crushing and hand-picking lump concentrate whenever this is desirable. In one plant screens and Akins classifiers have displaced the log washers.

Weight recovery in modern Mesabi washing plants averages about 65% on crude. Costs are 5 to 10¢ per ton treated.

DeVaney and Coghill (*RI 3148*) point out that bowl-rake product, which contains 14 to 18% SiO_2, must be admixed with high-grade material to make it salable, and that when the product runs much higher in silica than this it may even be wasted. They report a test on such a product, assaying 44% Fe and 34% SiO_2, in which the material was sorted in a hindered-settling classifier, classifier overflow was wasted, six spigot products were tabled separately, with regrind and retabling of middling, resulting in a recovery of 46% by weight in a concentrate assaying 63% Fe and 9% insol., with an additional recovery of 55% by weight from the 20% of middling made in the primary runs, in a concentrate assaying 61% Fe. Tailing from the primary run assayed 17% Fe. Their results indicate that the early spigots of the classifier could be taken as concentrate directly, leaving only the later spigots for tabling. They estimate, on the basis of commercial table performances on similar materials, that table capacities would average 2.5 tons feed per hr. See also Sec. 10, Art. 7.

Oliver Iron Mining Co., Canisteo washing plant. Fig. 84 (*142 #5 J 36*).

Location: Coleraine, Minn.
Ore: Loose mixture of soft hematite and taconite sand.
Cost: $0.06 to $0.15 per ton of feed is an average range (1938) for this type of plant.

12. 24-in. conveyors to ore cars for shipment.

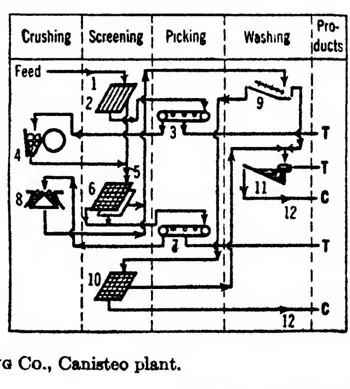

Fig. 84. Oliver Iron Mining Co., Canisteo plant.

Concentrating plants for iron ores must be mechanically efficient, cheap to operate, and capable of handling large tonnages. Of the standard base price of $4.50 per ton (1936) for non-Bessemer ore of 51.5% natural iron content at lower Lake ports, $1.74 is freight, leaving a net value at the mine of $2.76. Out of this must come mining and concentrating costs royalties, and a multitude of onerous taxes. Consequently the ratio of concentration must

be low, if any profit at all is to come out of the operation. From an economic standpoint an ore or a concentrating process that requires fine crushing or grinding of any considerable part of the feed tonnage to effect separation is *prima facie* unsuitable at present.

The typical Lake Superior concentrating plant is a combination comprising coarse concentrators, normally jigs, for rejecting coarse gangue, and washing apparatus for removing the fine free sand and the fine gangue produced by crushing. Holt (*22 #12 MCJ 20*) gives a generalized flowsheet (Fig. 85), noting that the types of concentrating machines used vary considerably throughout the district. The Charleson plant (Fig. 86) is a modern plant of this type. In a new jig plant (*141 #2 J 82*) ore is crushed to <1/2-in.; jigged unsized in Conset jigs, which make coarse concentrate and coarse tailing;

a fine tailing which is deslimed in a Hydroseparator and a rake classifier in series, with classifier sands returned to the jigs; and a middling which is ground in rod mills, deslimed in a rake classifier, and the resulting sand recirculated to the jigs. The advantageous results are: an increase in jig efficiency because the relatively high proportion of sand in the feed tends to produce heavy-medium character in the jig bed; and increased recovery of iron. Jig concentrate sinters readily. Weight recovery in the jigging plants is about 50% of the crude. The Harrison plant of Butler Bros. employs a sink-float separating cone in place of coarse jigs, thus doing away with 3 screening and 3 jigging operations as compared to Fig. 85, and making a lower-grade tailing than can be made on jigs treating the same material (see Sec. 11, Art. 29). The roasting-magnetic plant of Butler Bros. is an experimental attack on the problem of treating high-grade jig tailing (containing much porous and consequently specifically light hematite particles), of which large tonnages are scattered through the western Mesabi district; it made exceptionally high grade concentrate and a good tailing for iron concentration, but costs were too high for present-day competition.

The number of plants on the Mesabi employing concentrators other than washers is relatively small, and concentrate shipped is only about one-eighth the tonnage of washed ore.

Charleson Iron Mining Co., Judd pit. Fig. 86 (C. H. Remer, Gen'l Sup't, *139 #3 J 38*).

Location: Taconite, Minn.
Ore: Banded hematite and partly decomposed taconite.
Capacity: 300 long t.p.h.
Assays: Feed, 30 to 35% Fe; concentrate, 52 to 53% Fe.
Recovery: 35 to 40%.
Power: 800 hp. under full load.

Summary. Two-stage crushing to 1/2-in. in closed circuit; washing at <1/2-in.: jigging at <1/4-in.

FIG. 86. CHARLESON IRON MINING CO., Judd pit.

Butler Bros., Harrison plant. Fig. 87 (*Q; 141 #9 J 34; 26 #9 MCJ 25*).

Location: Cooley, Minn.
Ore: Concentrating ore, comprising soft hematite with taconite and sand.
Assays: Feed: 40 to 45% Fe; concentrate, 59% Fe, 7 to 9% SiO_2.
Recovery: 80 to 85% Fe.
Water is pumped 1 mi. from Pickerel Lake.
Power: Purchased at 2,200 volts; motors, 440-volt, 60-cycle; CONSUMPTION, 18 hp-hr. per ton.
Running time: 95%.
Mill building: Level site. Steel and concrete, galvanized-iron partial enclosure. Unheated (unused in winter).
Transportation: Mine (open-pit) to mill, 1 mi. Ore is trucked in pit to a conveyor-loading hopper, thence by conveyor to rim of pit, thence by dump car and locomotive to mill. Concentrate (7% moisture) is shipped to lower Great Lakes furnaces (Chicago, Cleveland).

Legend for Fig. 87:

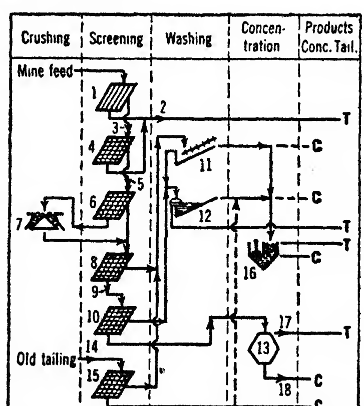
15. 1 @ 4×8-ft. vibrating screen, 1/4-in. aperture.
16. 7 Bendelari and 1 Conset jigs.
17. 2 @ 4×6-ft. vibrating draining screens, 2-mm. apertures; 2 @ 5×16-ft. 2-mm. vibrating washing screens; washings to medium-recovery plant.



18. 2 @ 4×6-ft. vibrating draining screens, 2-mm. cloth; 2 @ 4×16-ft. 2-mm. vibrating washing screens; washings to medium-recovery plant.

FIG. 87. BUTLER BROS., Harrison cone plant.

Summary. Run-of-mine material >3 1/2-in. rejected by screening; 3 1/2~1 1/4-in. crushed to <1 1/4-in. and screened on 1/4-in. 1 1/4~1/4-in. treated in sink-float cone making concentrate and tailing. <1/4-in. washed in log washers and bowl classifiers, the latter making overflow tailing, and both sending washed products to jigs which make concentrate and tailing.

Butler Bros. roasting-magnetic plant. Fig. 88 (J. J. Craig, Sup't, *139 #1 J 48; 153 A 645.*

Location: Cooley, Minn.

Ore: <1 1/4-in. jig tailing consisting principally of comparatively clean hematite, comparatively clean silica, taconite, and locked combinations of the three.

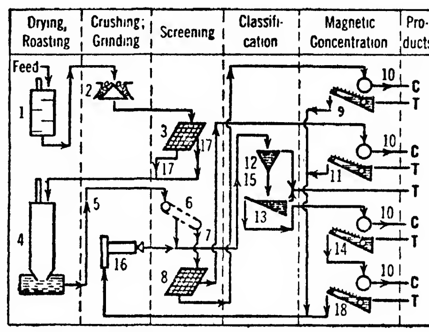
Capacity: 265 tons feed per 24 hrs.; limited by the furnace.

Assays: Feed, 47% Fe; concentrate, 62.6%; SiO_2, 11.4%; P, 0.045%; <100-m. size held at 10% or less; tailing, 20.6% Fe, including 6% magnetic Fe.

Recovery: 90% based on furnace product; recovery of magnetic iron, 98.9%.

Ratio of concentration: 1.5 : 1.

Costs: The operation is marginal, *i.e.*, dependent upon feeds against which mining cost need not be charged. Its inception was experimental. Roasting cost, Sept. 1935: fuel, $0.555 per ton roasted; power, 0.050; labor, 0.072; total, $0.677.



Legend for Fig. 88:

1. Vertical-shaft drier. Oil fuel. Moisture reduced from 8 or 10 to 3%.
2. Crusher.
3. Screen, 3/4-in. aperture.
4. Vertical-shaft roasting furnace with water-quench at base. Oil fuel; oil vapor for reduction from Fe_2O_3 to Fe_3O_4. Reduction must be substantially complete (average conversion is 91%), a "skin roast" does not confer sufficient magnetic force to move the mass of unconverted hematite. Iron silicates do not reduce.
5. 2 pipe conveyors in series.
6. Trommel, 3/16-in. aperture.
7. Bucket elevator.
8. Vibrating screen, 5/16-in. aperture.
9. Magnetic cobber, 31(diam.)×32-in. drums; see Sec. 13, Art. 4.
10. Conveyor; 220-volt a.-c. demagnetizing coil surrounding a 3 1/2-in. Micarta tube through which pulp flows; bin; mixed with other ores before shipment. Demagnetization enables water to drain and facilitates mixing.
11. As (9).
12. Settling cone.
13. Rake classifier.
14. As (9), 2 in parallel.
15. Sand pump.
16. 1 @ 5×4-ft. ball mill.
17. Separate elevators to separate feed bins.
18. As (9).

FIG. 88. BUTLER BROS., roasting-magnetic plant.

Summary. One-stage crushing, reducing roast, wet magnetic separation with regrind and reconcentration of middling.

Recovery by this method is high, as is also the grade of concentrate, but costs at present are so high, compared with those for jigging and washing, as to make concentrate so produced of marginal value so long as concentrate from the latter plants sets the market price.

Magnetic plants. The Eastern magnetites have been mined spasmodically for more than 100 years. The WITHERBEE, SHERMAN Co. dry-magnetic mills (*Ed. 1*) are typical of the method used for many years on the coarsely crystalline, lower-grade ores. Modern demands for higher grade of concentrate with reduced phosphorus have made necessary finer crushing before making final concentrate, and the adoption of wet magnetic separators. All of the magnetite ores contain martite, the permeability of which is too low for the low-intensity separators used for magnetite; where the amount of martite is sufficiently large to justify saving it, gravity concentration supplements magnetic, as at ALAN WOOD. The ore at the BETHLEHEM STEEL property at Cornwall, Pa., contains chalcopyrite as well as magnetite, and the tailing from wet magnetic concentration is, therefore, reground and floated.

Costs of treatment at the eastern mills are about 20 to 25¢ per ton of feed.

Most magnetite concentrate is too fine for blast-furnace treatment without sintering, but sintered, the high-iron (>68%) low-silica product commands a premium. On the other hand, Eastern magnetite concentrate suffers at present from a freight differential to the steel centers.

The principle followed in concentration of all magnetite ores is to scalp out middling at coarse sizes at relatively high intensities and reject tailing, then to recrush the middling and direct the concentration to the production of high-grade concentrate from this enriched feed. This principle was carried to its logical extreme at the MESABI IRON Co. mill, which was designed to treat the low-grade magnetic ores of the eastern Mesabi field. The mill was a technical success and represents the best method known to date for concentrating this

ore; it has been shut down, however, since 1924 because concentrate so produced cannot compete in that field with hematite ore and concentrate.

Magnetic concentrate other than the finest must, normally, be cleaned on gravity concentrators if high-grade concentrate is wanted, because the magnetic machines put much locked middling in concentrate.

Warren Foundry & Pipe Corp. Fig. 89 (*Q* by F. Radel, Sup't).

Location: Wharton, N. J.

Ore: Magnetite, 62%; apatite, 3%; with feldspars, hornblende, and biotite; there is a negligible amount of quartz and no pyrite or martite.

Capacity: 238 tons per shift.

Assays: Feed, 45% Fe; concentrate, >67% Fe; tailing, ±7% Fe.

Recovery: 93%.

Ratio of concentration, 1.72 : 1.

Water: None used.

Power: Purchased; comes 4 mi. at 33,000 volts; motors, 440-volt; magnets, 250-volt; CONSUMPTION, 8.3 hp-hr. per ton milled.

Labor: 22.2 tons per man-shift; repairs average 15 to 20% of total labor.

Running time: 81%; lost time due to repairs.

Mill building: Frame with some concrete and steel underpinning; wood floors. Machinery handled by chain blocks.

Distances: 1,000 ft. mine to mill by railroad cars; 75-mi. rail haul to smelter.

Tailing disposal: Coarse tailing sold for concrete aggregate; fine tailing flushed through launder with mine water to an adjacent swamp.

Legend for Fig. 89:

24. 1 as (15).
25. 1 @ 2-belt Ball-Norton magnetic separator.

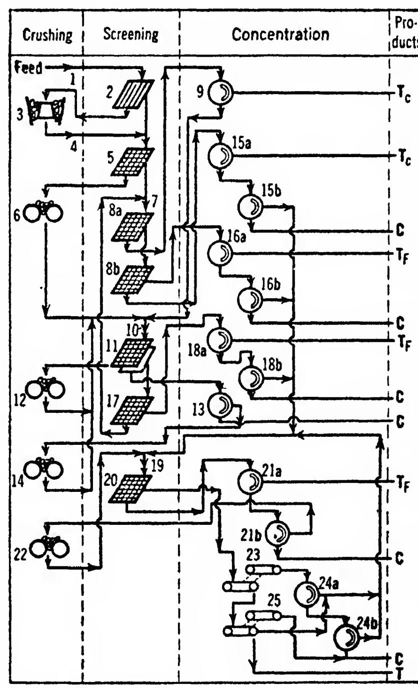

FIG. 89. WARREN FOUNDRY & PIPE CORP.

Summary. Three-stage crushing in gyratory and rolls to <3/4-in. Dry magnetic concentration of primary products at 4 sizes, rejecting tailing at all sizes and making concentrate at sizes below 1/8-in. Middling recrushed to <1/8-in. and retreated with cleaning of concentrate and recirculation of cleaner middling to the crushing circuit.

This is the only completely dry magnetic mill still operating on magnetite ore in the United States. The older mills of REPUBLIC STEEL Co. at Mineville, N. Y., are still primarily dry concentrators, but wet-magnetic separation has been installed for the fine sizes; the new mill of REPUBLIC at Port Henry uses wet-magnetic separators on all machines making finished concentrate.

Mesabi Iron Co. Fig. 90 (*Q; 23 LSMI 111*).

Location: Babbitt, Minn.
Ore: Magnetite in ferruginous chert (taconite).
Capacity: See flowsheet. Ultimate planned, 75,000 tons per 24 hr.
Assays: See Table 60.
Recovery, magnetic iron: 80%.

Fig. 90. Mesabi Iron Co.

Summary. Four-stage crushing from steam-shovel size to 6-m. with tailing rejection started at 2-in. size and comprising 28% of total feed in the 2-in.∼6-m. range; further rejection of 20% on <6-m. feed before regrinding. Rough primary concentrate reground and cleaned at 48∼150- and <150-m. Sand-cleaner concentrate reground to 150 *mog* and then recleaned in two stages. Concentrate sintered before shipment.

Arrangement of machines is shown in Fig. 91. The features of particular interest are the arrangement of the breakers in a rock pit, 50 ft. square by 105 ft. deep; the use of conveyors for all elevation of ore; and the use of stock piles instead of bins for storage.

57. 50-ft. thickener.
58. Dewatering drag. Feed (combined table tailing), 3.5 to 6% Fe.

Summary. Four-stage crushing from >16-in. to <5/8-in. with >1/4-in. product roughed magnetically at 4 sizes from >2 1/4-in. to >1/4-in. and nonmagnetic tailing discharged for sizing and sale as aggregate stone. Enriched material crushed to <1/4-in. and concentrated successively on magnetic and gravity roughers, with rough concentrates cleaned on gravity concentrators. All middling reground in tumbling mills to <12-m. and reconcentrated as on the primary stream, with middling recirculated to the grinding circuit.

Hvitafors concentrator. Fig. 94 (*72 Gl 1073*).

Location: Hvitafors, Malmberget, N. Sweden.
Ore: Middle products from 4 other concentrators treating coarse mine ore by hand-picking and magnetic separators. Hvitafors feed contains about 75% magnetite with some feebly magnetic specular hematite; nearly 5% apatite; remainder, gangue minerals. Maximum size, <35 mm.
Capacity: 80 tons per hr.

Assays: Feed: Fe, 40%, P, 0.9%; concentrate I (about 3/4 of total output): 70% Fe, 0.02% P (max.); concentrate II (about 1/4 of total output): 65% Fe; 0.4% P; concentrate with 71.4% Fe has been made.
Recovery: 80%.
Ratio of concentration: 2.22 : 1.

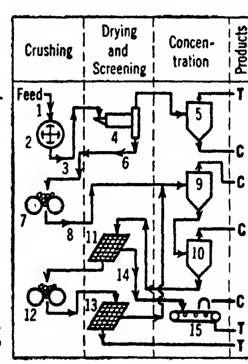

FIG. 95. PEGNITZ mill.

Summary. Differential grinding; concentration by air classification followed by high-intensity magnetic separation of the classifier sands.

Alabama iron ores are of two principal varieties, *viz.*, (1) the red ores of the Birmingham district, and (2) the brown ores in an area comprising an irregular annulus surrounding the red ore. The red ores that have been mined are mostly of shipping grade (45 to 50% Fe), the Alabama furnaces being able to tolerate this lower grade, with correspondingly higher silica content, economically, on account of the lime content of the ore and the

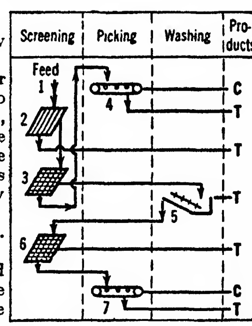
resulting self-fluxing character. The structure of the ore also, comprising onionlike shells of very fine hematite, lime carbonate, and clay consolidated around markedly larger grains of quartz, has prevented mining of the lower grades of ore on account of inability to wash or otherwise concentrate it. (See p. 150 for a record of laboratory attempts to solve this problem.) The BROWN ORES comprise hydrated iron oxides occurring in more or less irregular deposits of highly variable extent in surface wash of clay, sand, and gravel. The iron mineral is concretionary and consequently harder than the clay and heavier than the sand and gravel; there is no true locking of valuable mineral and gangue. Consequently treatment comprises disintegration and washing away of the clay and fine sand from the harder iron nodules and gravel, and gravity concentration to separate iron minerals and gravel.

The size and complexity of the plants depend upon the size of the deposits and the extent of admixture of the gravel. In all cases selective mining plays a large part; isolated small deposits in which gravel cannot be largely separated in mining are not workable, except under circumstances in which the ore can be transported economically to a plant treating large enough tonnages of gravel-bearing ore to justify jigs.

Three characteristic types of plants are employed, *viz.*, (1) screening plants, (2) washing plants, (3) jig plants. (See also Fig. 97.)

Screening plant. Feed, usually trucked in, is dumped into a chute set below the angle of repose and is washed therethrough and over a grizzly (3- to 4-in. aperture) by a stream from a nozzle. Large gravel, clay balls, and other waste are picked off the grizzly and large lumps of ore are sledged through. Grizzly undersize goes to a revolving washing screen, 4 to 5 ft. diam. $\times$ 10 to 14 ft. long, with $^1/_2$- to 1-in. aperture plate covered with $^1/_8$- to $^3/_{16}$-in. wire cloth. Oversize is hand picked to remove clay balls and gravel, the residue being concentrate; undersize is wasted. WATER CONSUMPTION is 150 to 350 g.p.m. for 50 to 150 tons feed per day. If the sand and finer ore nodules are tightly clay-bound, more vigorous disintegration than can be effected by this method is required.

Washing plants. A typical washing plant for 100 to 150 cyd. of crude per hr. is shown in Fig. 96 (*108 P 458; A TP 860*). WATER REQUIREMENT is about 2,000 g.p.t. of feed.



Legend for Fig. 96:

1. Ore comes from one or more open pits by side-dump cars or by trucks.

2. Heavy rail grizzly, 1 $^1/_2$ ft. wide, 4-in. spacing, 1 $^1/_2$ to 2 in. per ft. slope, forming a false bottom for a V-shaped receiving hopper, 5 to 6 ft. wide at the top, 50 to 60 ft. long, 2 to 3 ft. deep at the upper end, bottom 1 $^1/_2$ ft. wide sloping 2 $^1/_2$ in. per ft. Feed is washed on the grizzly with a stream from a nozzle, waste is picked off, and oversize ore is sledged through. If the amount of oversize requiring sledging is sufficient to warrant a crusher of the roll or fine gyratory type, one may be installed to crush oversize and deliver to (3).

3. Conical revolving stone screen of one or two sections, 10 to 16 ft. long, 2- to 3- or 2- and 3-in. apertures; strong washing spray.

4. Picking belt or pan conveyor, about 24-in. Clay balls and gravel removed. Oversize may be recrushed to 2 in. in rolls or fine gyratory and the crushed product be rescreened and rinsed on a fine screen (undersize to waste) before being sent to concentrate bins.

5. 2 @ 20- to 30-ft. double-log washers; square or octagonal welded-plate logs, 10 to 18 in. "diameter," with steel blades about 9 to 10 in. long, 5 $^1/_4$ in. wide, and 1 $^1/_4$ in. thick bolted to angles welded to the logs so as to form a single or double spiral. Slope of logs and trough bottom is about 1 in. per ft. Sheet-steel trough ranges from 4 ft. deep at lower end to 2 ft. deep at upper, is flat-bottomed and wide enough to give about 6-in. clearance of blades at sides. Logs are gear-driven at 12 to 20 r.p.m. An adjustable overflow gate is provided.

6. 2 @ 32- and 42-in.$\times$8-ft. revolving screen; inner shell is plate $^3/_8$- to $^1/_2$-$\times$1 $^1/_4$- to 2-in. slotted openings, outer is lighter plate with $^1/_{16}$- to $^3/_{32}\times ^1/_2$-in. slots. A strong washing spray is used. Oversizes are combined.

7. Picking belt or pan conveyor, about 24-in. Clay balls and gravel removed, comprising about 50% of the belt feed.

FIG. 96. Alabama brown-ore washing plant.

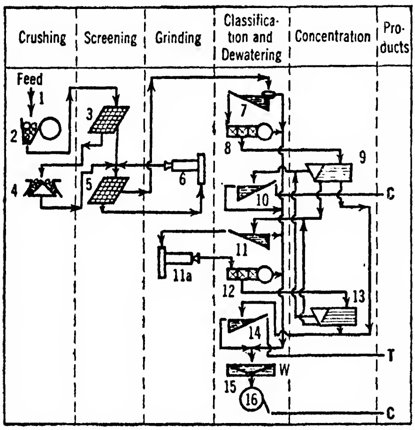
POWER installation is about 100 hp. for the plant shown, including pumps; add about 25 hp. per crusher, if these are used. RECOVERY, as defined in the field, is the inverse of the ratio of concentration and ranges from $^1/_3$ to $^1/_{12}$, averaging about $^1/_5$. CONCENTRATE assays 42 to 50% Fe, about 1% or less of Mn, and 0.5 to 1% P. COST of concentrate, with a recovery not less than $^1/_6$, was from \$0.50 to \$0.75 per ton in 1914.

Jig plant differs from that shown in Fig. 96, in that the oversize from the sand screen (item 6) is sent to jigs. Hancock jigs have been used on feeds ranging from $^1/_{16}$- to $^3/_4$- or 1-in., but present practice is to size rather closely (*e.g.*, 1$\sim ^3/_4$-in., $^3/_4 \sim ^1/_2$-in., $^1/_2 \sim ^1/_4$-in., and $^1/_4 \sim ^1/_{16}$-in.) and treat the grades on separate cells of a jig of the McLanahan type.

Capacity of such jigs is 20 to 25 tons per cell Clay should be removed from the feed as much as is economically possible.

Fine tailing from the washing plants contains considerable fine ore. Various attempts have been made at recovery. Tabling after hydraulic classification gives the best results, but has in general proved too expensive to justify installations.

Spaulding concentrator (Fig. 97), built in 1943, is a red-ore concentrating plant built under war-time impetus. Operating data are not available. The principle of treatment is to scuff off the very fine iron mineral from silica by light treatment in rod mills, and to recover it, while at the same time granular iron mineral is saved on tables.



Legend for Fig. 97:

	100.00	31.99	6.04	100.00	100.00

Summary. Primary crushing to <200-mm. Hand-picking down to 40-mm. Stage sizing (without further crushing) and jigging down to 2-mm. Fines deslimed; sand dried and magnetically separated; slimes wasted. All middlings recrushed to <6-mm. and recirculated. Other mills of Sieg district employ Harz-type jigs at 45-mm. and below, with hand-picking of concentrates down to 18-mm., and separate treatment for middlings.

Eupel mill. Fig. 99 (*57 SuE 292*).

Location: Sieg district, Rhenish Prussia.

Ore: Roasted mangano-siderite similar to that treated in Alte Hütte mill (Fig. 98).

Capacity: 30 met. tons roasted ore per hr. (approx. equivalent to 40 tons raw ore).

Assays and weights of products at two other mills using similar methods on same type of ore are given in Table 62; at mill *A*, recovery of Fe was 93.5%; at mill *B*, 91%.

17. As (10).

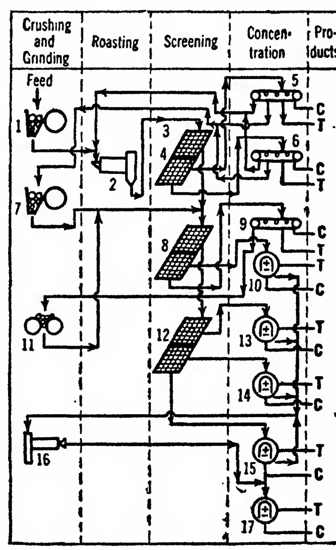

FIG. 99. EUPEL mill.

Summary. Primary crushing to 120-mm.; roasting to render material magnetic; sizing to 6 grades; hand-picking down to 35-mm., magnetic concentration of smaller sizes; all primary magnetic middlings combined, reground, and rerun once.

Experimental. Much testing work has been done against the day when the reserves of high-grade ores of the Mesabi and southern field, the wash ores, and the easily concentratable hematities and magnetites are exhausted. Treatment of low-grade ores of coarse dissemination presents no technical difficulties; the magnetites can be treated in the present mills without change; the nonmagnetic oxides are treatable as at the roasting-magnetic plant of BUTLER BROS. (Fig. 88); the practical question is simply that of ratio of concentration. The finely disseminated low-grade magnetites will now yield high-grade concentrate at a cost of about \$3.50 per ton, according to Davis' analysis (*22 #1 MCJ 28*)

a Products from recrushed middlings.

of the Mesabi Iron operation. The treatment of nonmagnetic material of corresponding grade and structure is not commercially promising despite that the roasting-magnetic principle is applicable. Such material must be sufficiently finely ground to at least expose, if not sever, the iron-mineral particles before roasting, which involves low-capacity roasting and high dust losses, plus dry grinding or drying of wet unroasted slimes, in addition to the Mesabi Iron costs.

Successful flotation of finely disseminated iron-oxide ores has not yet been reported, even in the laboratory. Fatty acids and their soaps will activate hematite (and probably some of the hydrated oxides) but slimes prevent selective flotation, and losses of expensively ground material are too high, if rejection of slime prior to flotation is practiced. Flotation of quartz gives promising results both technically and economically.

Promising test results are reported on some special simpler materials. DeVaney and Coghill (*IC 3052*) worked with wash-ore tailing which, discharged at about 20% Fe, had undergone natural concentration in ponds until the granular residues assayed 45 to 50% Fe. They found that with such feed assaying 45% Fe, jigging the >10-m. fraction, classifying <10-m. hydraulically, discarding classifier overflow, and tabling the spigot products yielded concentrate assaying 61% Fe and a 25% tailing, constituting 76% recovery. By roasting-magnetic treatment, tailing as low as 2.2% Fe and 64.6% Fe in concentrate were made (97% recovery), but costs were, of course, much higher.

Alabama oölitic ores and the fossil ores of the same district comprise onionlike shells of admixed limy clay and iron oxides surrounding cores of relatively coarse sand grains. Gravity concentration and flotation have failed to separate the silica when the material is sufficiently ground by normal methods to effect severance. Roasting-magnetic treatment of such a product yields concentrate assaying 50 to 60% Fe and 8 to 20% SiO_2 with silica rejections of 50 to 95% and recoveries of 85 to 97% (*Bul 278 USBM*) but at a probable cost that would be uneconomic. Differential grinding of <$^3/_8$-in. feed in lightly loaded rod or slug mills, which shells off the iron minerals without breaking the quartz grains materially, using a mechanical classifier to overflow concentrate, and tabling the classifier sands after hydraulic sorting yielded concentrate assaying 48.7% Fe, 12.5% insol., and 5.2% CaO with a recovery of 82.5% of the iron from a feed assaying 36.6% Fe, 27.7% insol., and 7.4% CaO (*RI 2937; RI 3523; 139 #11 J 43*). See Fig. 97.

Manganiferous ores of the Cuyuna range were tested by DeVaney and Clemmer (*RI 3045*). The material tested was a BLACK ORE (Art. 31). Classification and tabling yielded concentrate assaying 35% Fe, 21% Mn, and 10% insol. (Mn recovery, 72%) from a feed carrying 32% Fe, 16% Mn and 20% insol. Flotation of a feed assaying 26% Fe, 23% Mn, and 19% insol. gave concentrate assaying 26% Fe, 29% Mn, and 10% insol. with a recovery of 68% of the Mn. Roasting-magnetic treatment in an endeavor to make a manganese product of ferromanganese grade (9 to 10 times as much Mn as Fe) was unsuccessful owing to the fact that 40% of the manganese was still locked with the iron at 325-m. Zappfe (*22 #11 MCJ 17*) mentions a roasting-leaching method for separation of manganese from these ores.

Flotation of wash-ore tailing. Searles (*UM*) reported flotation tests on wash-ore tailings of which sizing-assay tests are shown in Table 63. Tests, using fatty-acid collectors ± oils, in alkaline pulps, were made on both original samples and on deslimed residues. The latter gave the poorer flotation results and a markedly higher over-all tailing. Two pounds oleic acid per ton, with 4 lb. sodium carbonate, yielded rough concentrate assaying 53.4% Fe and tailing of 3.6% Fe, with 34.4% weight recovery and 88.7% recovery of iron; reflotation with the addition of 0.7 lb. soda ash per ton of original feed yielded a concentrate assaying 60.5% Fe. No locked test was made. Reagent cost would be excessive, however, from an economic standpoint; assuming 4 tons original feed per ton of concentrate and prices of 1.1¢ per lb. for soda ash and 9.5¢ for oleic acid, the reagent cost per ton of concentrate

would be 93.6¢. Further tests using various substantially neutral hydrocarbons (both from petroleum and from coal tar) as partial substitutes for oleic acid showed possibilities of some reduction in reagent cost, the best results being obtained with a mixture of 9 parts Barrett 634 and 1 part oleic in an amount equivalent to 4.3 lb. per ton of feed, with 1 lb. NaOH, which yielded 56.6% Fe in concentrate, 24.0% Fe in tailing (from a richer feed than shown in Table 63), and a recovery of 75%. A reagent made by reconstructing a fatty acid with sulphur, when used in an amount equivalent to 0.6 lb. per ton of feed, with 1 lb. sodium silicate, showed 60 to 75% recovery in a concentrate assaying 56 to 57% Fe, and a tailing assaying 25 to 30% Fe, on a 42% feed; on feeds of 18 to 25% Fe, recoveries were 48 to 73%, concentrate assays 53.4 to 57.4% Fe, and tailing assays 6.6 to 16.2% Fe. Searles estimates the reagent cost for such operation at about 15¢ per ton of concentrate.

Total	.....	100.0	19.7	100.0	100.0	15.1	100.0	100.0	18.6	100.0	100.0	18.5	100.0

Keck (*139 #4 J 46*) reports laboratory flotation of gypsum (S bearer) from hematite with sodium oleyl sulphate, reducing the gypsum content from 0.8% to 0.08%; also that with sodium oleate and sodium silicate the gypsum floats first; he says also that ammonium palmolate (NH_4 soap of palm oil) reduced the P content (apatite) from 0.32% in feed to 0.18% in tailing, the float assaying 0.55% P.

The obvious avenue of attack on coarsely disseminated ore would seem to be table flotation (Sec. 12, Art. 30) of deslimed feed, using a neutral oil with a light loading of fatty acid for a collector. This would tend to grade up concentrate and reduce the expense of collector and size preparation, and the actual separation would be high-capacity operation and correspondingly cheap.

29. LEAD AND ZINC

Occasionally one of these metals is found in economic quantities in an ore in which the other is lacking or is but a minor constituent; such occurrence is, however, so rare that the localities can almost be counted on the fingers of one hand, *e.g.*, lead in southeastern Missouri, Leadville, Colo., and Tintic, Utah, and zinc at Mascot, Tenn., Franklin Furnace, N. J., and southwestern Wisconsin. The usual ores contain galena and sphalerite, many carry important amounts of silver; minor amounts of copper are not uncommon and are usually accompanied by minor quantities of gold; pyrite and pyrrhotite are common associates; carbonates and quartz are the most usual rock-forming gangue minerals, but other gangue associates are legion.

Lead

Uses. The principal consumption of lead is as the metal and peroxide in storage batteries, as metal in cable coverings, and as white lead ($x PbCO_3 \cdot y Pb(OH)_2$) in paint. The metal, on account of its noncorrosive properties, also finds wide use for pipes, flashing, etc., in buildings. Considerable metallic lead is used for ammunition making. Important lead alloys are solder, pewter, type metal, bearing metal, and various low-fusing metals. The oxides PbO and Pb_3O_4 are used in glass, rubber, and paint manufacture. Lead arsenate is used as an insecticide, but calcium arsenate is more common.

Ores. The economic minerals are galena, cerussite, anglesite, and pyromorphite. Galena ores comprise the great majority. There are three general classes: (*a*) those containing lead alone as an economic metal; (*b*) lead-zinc ores; (*c*) lead-silver ores. Calcite, dolomite, and pyrite are the common gangue minerals of the first two classes, quartz of the third class.

Production of lead in the United States, by states, is given in Table 64. World production is shown in Table 65.

Selling. See Art. 50. New York prices for pig lead averaged 6.01¢ per lb. for the 10-yr. period 1913–1922; 6.56¢, 1923–1932; and 4.97¢, 1933–1942. Yearly averages: 1929, 6.83¢; 1932, 3.18¢; 1937, 6.01¢; 1938, 4.74¢. St. Louis prices average 0.12 to 0.14¢ below New York. Yearly average Joplin prices for lead concentrates (Art. 50) were: $89.05 per short ton in 1929; 1932, $34.78; 1937, $69.34; 1938, $51.61.

Zinc

Uses. The important uses are in coating iron to protect it against corrosion (GALVANIZING); BRASS making (zinc, 20 to 50%; copper, 80 to 50% ± small amounts of tin, lead, and iron); as a constituent of other alloys such as GERMAN SILVER (copper, nickel, zinc) and WHITE METAL (zinc and copper, zinc predominating); in zinc-white pigment; as the positive pole or plate in electrical batteries; zinc shavings and dust in cyanide precipitation; gutters, household utensils, etc., where resistance to corrosion by air and water is desirable.

Ores. The economic minerals are sphalerite, smithsonite, calamine, franklinite, willemite, and zincite. There are several distinct types of ores. Argentiferous and auriferous zinc sulphides with or without some lead, copper, and iron sulphides in quartzose gangue are typical of the Rocky Mountain deposits. Sphalerite alone or with galena and, usually, with some pyrite in limestone are typical of the Mississippi Valley deposits. Zinc as-

franklinite, willemite, and zincite in a white, crystalline limestone is the characteristic occurrence in New Jersey. Sulphide ore bodies may be overlain by deposits of smithsonite, calamine, and hydrozincite. Such deposits are often more valuable than the primary sulphides, both for the reason that they are more concentrated and that their metallurgical treatment is simpler.

Production in the United States is shown in Table 66; world production in Table 67.

Selling. See Art. 50. New York PRICES for Prime Western zinc averaged 8.35¢ per lb. for the 10-year period 1913–1922; 6.14¢, 1923–1932; and 5.95¢, 1933–1942. Yearly averages: 1929, 6.84¢; 1932, 3.25¢; 1937, 6.87¢; 1938, 4.99¢. St. Louis prices average 0.4 to 0.6¢ below New York. Yearly average Joplin prices for zinc concentrates (Art. 50) were: $42.39 per short ton in 1929; 1932, $17.83; 1937, $39.87; 1938, $27.83.

Treatment of lead and zinc ores. The coarsely disseminated ores of lead, lead-silver, and lead-zinc, with gangue of average specific gravity (2.6 to 2.8), yield important quantities of high-grade lead concentrate by gravity concentration on jigs and/or tables, while flotation is used to recover the balance of the metallic values and, when necessary, to separate galena from sphalerite. Coarsely disseminated sphalerite ore is similarly treated, except that in one plant (AMERICAN ZINC Co.) tailing is roughed out at sizes up to 1 1/2-in. by sink-float treatment, and zinc is roughed out of the resultant middling by jigs, before flotation is applied to scavenge the fine sphalerite With heavy gangues zinc

minerals cannot be separated successfully by gravity methods. Sulphide ores of medium and fine dissemination, whether simple or complex, are first ground to flotation size (say 35 to 48 *mog* or as much finer as is necessary to free the sulphides), and are then floated by differential methods. Copper sulphides are ordinarily permitted to go with the lead, and pyrite is also, if it carries precious metals. Oxidized lead ores yield much better recoveries by gravity concentration than by flotation, provided the lead minerals free at sand sizes, hence gravity concentration is an important element in such flowsheets; oxidized zinc ores are so diverse in mineralogical composition that generalization as to treatment methods is not justified.

A typical lead, zinc, or lead-zinc flowsheet for coarsely disseminated ores (excluding such ores as American Zinc) comprises in order, crushing, gravity concentration, grinding and flotation. Crushing is usually three-stage, with jaw or gyratory for the primary, reduction gyratory or standard cone for the secondary, and short-head cone or rolls in closed circuit for the final stage to gravity-concentration feed size. Gravity concentration employs jigs and/or tables; the feed is usually long-range, preparation involving only desliming, to prevent dilution. Grinding is one-stage with the simple ores, two-stage with complex ores, the second stage usually being a middling regrind. Flotation is normally two-stage rougher-scavenger flow on the primary run for each sulphide; cleanings range from one to four. Ores of medium dissemination normally have two-stage crushing and two-stage grinding (one of which may be middling regrind); flotation tends toward more stages in roughing (prolonged rather than intense treatment) and averages less cleaning steps, probably because of relatively higher grade rougher concentrate and because the possibilities of extremely high grade concentrate do not, in general, justify the attempt to produce it. For finely disseminated ores up to four-stage crushing and four-stage grinding (one middling regrind) are practiced; flotation tends toward two-stage roughing and two cleaning steps on each metal.

For treatment of highly complex ores containing gold and silver see Art. 22.

Products. Assays and recoveries at a number of mills are given in Table 68. Gravity galena concentrate assays, in general, from 75 to 80% Pb; flotation concentrate at Pend

a Part gravity lead. *b* Gravity. *c* Franklinite. *d* Willemite-zincite.

Oreille and Trepca runs as high as 80% lead, but this is unique; flotation lead from coarsely disseminated ores such as Broken Hill and S. E. Missouri ranges in assay from 70 to 75%, but the more usual range for medium and fine disseminations is 60 to 65%. Gravity galena sand tailing at Bonne Terre, with coarse dissemination, assays 0.11% Pb; with medium dissemination and relatively fine grinding (65 *mog*) flotation tailing of 0.15 to 0.3% is usual; coarser grinding (35 *mog*) even with coarsely disseminated ores runs lead flotation tailing up to 0.6 to 0.8% Pb; with very finely disseminated ore and consequent over-long time for oxidation and other interfering surface reactions to occur, tailing rises to 1.5 to 1.8% (Mount Isa). Lead recoveries of 95 to 98% are not uncommon, even with relatively high tailing, on account of the fact that feed assays run, normally, in the range of 3 to 10%; recoveries as low as the upper 80's are unusual.

Assays of zinc concentrate, substantially all flotation, cluster in the fifties, with the majority below 55% Zn. Tailing below 0.5% is unusual; at the majority of mills the range is between 1.0 and 1.5%, and where grade of concentrate is important, *i.e.*, where the distance to the smelter is great, tailing of 2 to 4% is made. Recoveries cluster in the range from 80 to 90%; higher figures correspond to special circumstances, such as that zinc is the only metal recovered (New Jersey Zinc, American Zinc), company smelters (Trepca, N. J. Zinc), and the like. Silver recovery in lead concentrate normally follows lead recovery but tends to run 5 to 10% lower; it may fall much lower, if any considerable part of the silver minerals is associated with sphalerite rather than galena.

Power consumption at lead and zinc mills varies widely, from about 13.5 hp-hr. per ton milled at American Zinc and 16.5 at White Bird, both simple zinc mills, to about 20 at Bonne Terre and Broken Hill, milling simple lead and coarsely disseminated lead-zinc ores, to upward of 40 at Mt. Isa, where the ore is very finely disseminated. In general, for a given type of mill, power consumption is higher the lower the daily tonnage. Power for crushing ranges from about 2 hp-hr. per ton for one-stage to 5 to 6 for 3-stage. Grinding consumes about 5 hp-hr. per ton for one-stage work on coarsely disseminated ores, following fine crushing, and when flotation is practiced at 35~48-m. maximum; the figure for normal 65-m. grinding following 2-stage crushing is from 10 to 15 hp-hr. per ton, and for 3-stage work to 80 or 85% <200-m. is upward of 20 to 25 hp-hr. per ton. Jigging and tabling combined consume between 1 and 2 hp-hr. per ton; flotation consumes between 5 and 10 hp-hr. for simple ores and 10 to 15 for complex ores requiring repeated cleaning.

Labor. Average of 17 plants is 25 tons per man-shift, with a range from 10 to 46, the higher figures corresponding to the larger plants; at 25% of the plants reported the figure lies between 20 and 25 and the median likewise falls in this range. Averages reported to the Bureau of Mines and published (*IC 6776*) without detail show 33 tons per man-shift for 14 mills producing lead as the principal metal, 13 tons for mills where zinc was the principal metal, and 21.4 tons for 83 zinc-lead plants.

Costs of milling range from about $0.50 per ton for simple lead or zinc ores to $1.50 per ton for small plants treating not too complex lead-silver-zinc ores. At the larger plants treating complex ores, costs cluster between $1.00 and $1.25 per ton milled.

St. Joseph Lead Co., Bonne Terre mill. Fig. 100 (*Q*; L. A. Delano, Mill Sup't; *138 J 286; IC 6658; 153 A 603*).

Location: Bonne Terre, Mo.

Ore: Galena in dolomite, with small amounts of sandstone and shale. Galena distribution is indicated by Table 69. Some of the galena is very finely disseminated.

Capacity: 2,400 tons per 24 hr.

Assays: Feed, 2.9% Pb; concentrates: gravity (about 52% by weight), 78.75% Pb; flotation, 73%; combined, 76.34%; tailing: gravity, 0.11%; flotation, 0.14 to 0.18%.

Recovery: 92%.

Ratio of concentration: 29 : 1.

Water from mine drainage and surface rainfall collected in a lake about 1/2 mi. from mill, whence there is gravity flow by pipe; power for supply, 1.8 hp-hr. per ton; consumption: 2.12 tons net per ton of ore, 72% reclaimed in circulation, 7.5 tons per ton milled.

Power purchased; comes 7 mi. from main substation at 6,600 volts; motors 220- and 440-volt 60-cycle; consumption, 19.6 hp-hr. per ton of ore milled, of which dry crushing is 34%; grinding, 20.6; tabling, 2.7; flotation, 16.6; concentrate disposal, 2.0; tailing disposal, 12.7; water supply, 8.7; lighting, 2.7%.

Labor: American; 95 tons per man-shift operating; 92 tons per man-shift on repairs.

Running time: 98.6%; principal cause of loss, mechanical trouble.

Mill building: Level site; wood, steel, and concrete; concrete floors in basement and main floor, wood above, all level. Heated by natural-gas Mogul stoves.

Machinery handling: Air hoist and crawl on lifting frame in primary crushing; chain blocks and crawl on I-beam over secondary crushers; electric hoist on lifting frame for rolls; chain blocks on coffin hoists for rod mills; manual labor and coffin hoists in concentration section.

Transportation distances: Mill at mine; 100 mi. mill to smelter; railroad at plant.

Tailing disposal: Combined tailing pumped 1 mi. to pond.

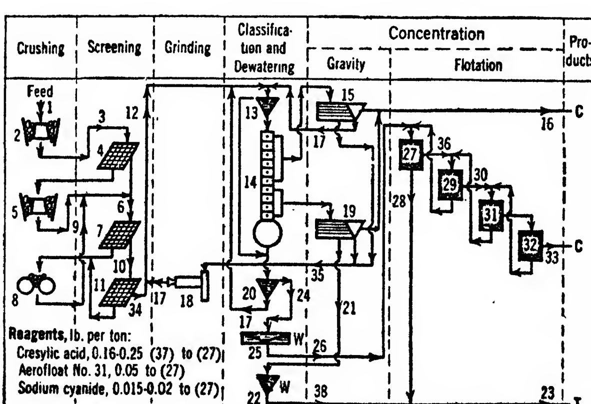

FIG. 100. ST. JOSEPH LEAD CO., Bonne Terre mill.

Legend for Fig. 100:

1. Direct from 2 3/4-ton mine skips. 60 skips per hr. max.
2. 1 @ 18-in. gyratory crusher, 2 3/8-in. open setting; concaves centered on eccentric center to produce finer product and compensate for one-side feeding. Mantle and concaves maintained by electric welding with hard-facing rods.
3. Conveyor No. 1(*a*); 36-in. suspended magnet over head pulley.
4. 1 @ 4×7-ft. 2-deck vibrating screen; upper deck 2×2-in. woven 3/8-in. rod for upper 4 ft., balance blank plate; lower deck 1 1/4×1 1/4-in. aperture, 3/16-in. wire; 860 r.p.m., 25° slope, 10-hp. motor, 4.2 kw. consumed.
5. 3 gyratory crushers, 2 operating full time, one about 30% full time; product about 5% >1-in., 50% <1/2-in.
6. Conveyor No. 2 with weightometer; 90-ton surge bin; conveyors 3, 4, and 5(*a*). Adjustable scrapers from conveyor No. 5 distribute feed to screens (7).
7. 12 @ 33×84-in. St. Joe-type vibrating screens, 0.095-in. square opening, 37° slope, 1,600 v.p.m., 3/16-in. drop on vibrator cams; 2 screens per 3-hp. motor.
8. 2 @ 54×24-in. rolls, set 1/16-in., one roll only driven, 73.4 r.p.m., 150-hp. motors; shells hard-faced by electric welding and similarly repaired. Circulating load 500 to 600%. Product of circuit about 90% <14-m.
9. Return is to conveyor No. 4(*a*).
10. Conveyors 6 and 7(*a*); sampler; conveyor No. 8.
11. 1 @ 3×5-ft. scalping screen, 0.0364-in. sq. aperture, 800 s.p.m., 12° slope.
12. Conveyor No. 9, *a* distributes by adjustable scrapers to mill bins; three sections from this point on; capacity ranges from 800 to 1,200 tons per section per 24 hr., with tailing increasing somewhat with increase in tonnage; notes following refer to one section; screw-controlled arc gate; 1 @ 24×38-in. pan-type apron feeder with 2-hp. motor pump No. 1(*b*).
13. 1 @ 80-in. Delano hydraulic deslimer, overflow, 11% solids.
14. 1 @ 19-spigot St. Joe hydraulic classifier, spigots 7/8- to 5/8-in. diam. See Table 70 for screen analyses and spigot distributions.
15. 4 shaking tables. 5/32-in. rubber covers and molded-rubber riffles, life 10 to 15 yr.
16. Dewatering drag; 4×1 1/2-ft. filter.
17. Pump No. 2(*b*).

a See Table 71. *b* See Table 72.

Legend for Fig. 100—Continued:

18. 1 @ 6 (diam.) × 4 1/2-ft. trunnion-type rod mill, 1 3/4-in. rods, 2-in. smooth liner, 30 to 40% solids.
19. 8 shaking tables (see 15). Number of tables sending tailing to regrind (item 15) or to waste changes with tailing assay.
20. Sand trap.
21. Pump No. 3 (*b*).
22. 1 @ 72-in. Delano hydraulic deslimer.
23. 2 pumps Nos. 4 and 5 (*b*) in series; 1% >14-m., 29% <200-m.
24. Combined from three sections.
25. 7 @ 6×50-ft. thickeners, underflow 32 to 35% solids; 2.7% >65-m., 58.9% <200-m.
26. Pump No. 6 (*b*); 1 @ 10 (diam.) × 6 1/2-ft. surge tank; 1 @ 7-way distributor.
27. 7 @ 3×36-ft. St. Joe pneumatic flotation cells in parallel, 4,000 cu. ft. per min., 3/4 lb. per sq. in., 18 hp., for 1 @ 36-ft. rougher and 1 @ 12-ft. cleaner (29); 24% solids; pH @ 8.3.
28. Pump No. 7 (*b*).
29. 7 @ 3×12-ft. St. Joe pneumatic flotation cells in parallel; overflow, 60 to 64% Pb; tailing, 4.5% Pb.
30. Pump No. 8 (*b*).
31. 2 @ 12-ft. St. Joe machines in series.
32. As (31). Overflow 74 to 77% Pb; tailing, 18% Pb.
33. 1 @ 50-ft. thickener, spigot, 75% solids; 1 @ 11 1/2×12-ft. drum filter, cake 12 to 14% moisture; 1 rotary drier, discharge 5.5 to 7% moisture, capacity 5,000 to 11,000 lb. per hr.
34. 94% <14-m.
35. Dewatered by shovel wheel.
36. 15 to 18% Pb.
37. More needed in summer than in winter. Recently some of the St. Joseph mills have substituted isopropyl xanthate for Aerofloat; some are adding a small amount of Na_2S to counteract superficial oxidation; others are using a mixture of hardwood creosote (75 parts) and amyl alcohol (25 parts) as frother rather than cresylic acid.
38. 2% >14-m., 1.5% <150-m.

8	30	3	1,120	50	5.7	6	1.5	4.5	3	27	65	10

Summary. Three-stage crushing run-of-mine to 0.1-in.; classification and tabling of sands with regrind of coarse tailing and fine middling in closed circuit with hydraulic classifiers and tables, and rejection of fine table tailing; flotation at 65-m. with triple cleaning. Flotation tailing is lowered by gravity removal of coarse galena.

This plant is typical of practice in the S. E. Missouri district. Gravity concentration pays its way by rejecting a fine sand tailing that is of lower grade than flotation makes, and by taking out approximately 50% of the total lead recovery as a high-grade concentrate without the loss that inevitably attends comminution of sulphides.

Hong Kong Mines, Ltd. Fig. 101 (*Tref 11/38*).

Location: Near Hong Kong, China.
Ore: Silver-bearing galena, 10 to 12% Pb, 1.5 to 3 oz. Ag, with a little sphalerite, in a siliceous gangue which is not particularly hard.
Capacity: 150 t.p.d.
Concentrate assay: 71% Pb and 17 oz. Ag.
Recovery: 95% Pb, 85% Ag.

b See Table 72.

Summary. One-stage open-circuit crushing to 1 1/2-in.; one-stage closed-circuit grinding to 65 *mog;* all-flotation concentration by a modified rougher-cleaner routing.

Legend for Fig. 101:

1. Jaw crusher.
1a. 100-ft. sorting belt, some waste removed; 525-ton bin.
2. 1 @ 6×6-ft. ball mill.
3. 1 @ 6-ft. classifier.
4. 1 @ 10-cell Denver Sub-A flotation machine: *a* = cells 5, 6; *b* = cells 7 to 10; *c* = cell 1; *d* = cell 2; *e* = cells 3, 4.

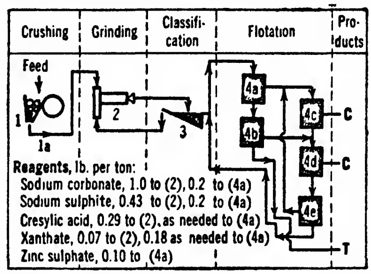

FIG. 101. HONG KONG MINES.

This plant has substantially the same problem as BONNE TERRE except that the tonnage is too small to justify the added complexity of a gravity section, and the silver content lessens somewhat the necessity for maximum grade of concentrate. The higher figure for lead recovery is an arithmetic result of higher-grade feed.

American Zinc Co. of Tennessee, Fig. 102 (*Q* by C. B. Strachan, Gen'l Sup't; *IC 6379; 139 #8 J 49; 141 #7 J 35*).

Location: Mascot, Tenn.
Ore: Blende, 5%; pyrite, 1%; galena, trace; greenockite, 0.5%; quartz, 8%, balance dolomite.
Capacity: 3,500 tons per 24 hr.
Assays: Feed, 2.9% Zn; concentrate, 62.7% Zn, 0.55% Fe, 0.09% Pb, 1.7% CaO; tailing, 0.225% Zn.
Recovery: 93.3%.
Ratio of concentration: 21.2 : 1.
Power: Purchased; comes 20 mi. at 66,000 volts; motors, 2,300- and 440-volt, 60-cycle; CONSUMPTION, 13.4 hp-hr. per ton milled.
Water: Source is a dam in Flat Creek, 2 mi. distant. Comes to mill by gravity through a ditch line. In process, 7.9 tons per ton of ore; reclaimed, 67%.
Labor: 38 tons per man-shift, operating plus maintenance.
Running time: 98% on 6-day-week basis.
Mill building: Level site. Steel and concrete with zinc-coated sheet roof and sheathing. Unheated.
Machinery handling: Power cranes in crushing section; hand cranes and chain blocks in concentrating mill.
Tailing disposal: All coarse and fine sand tailing sold. Slime to dam near mill.
Distances: Mines to mill: 2,000 ft. by aerial tram; 15 mi. by standard-gage railroad. Concentrate shipped 400 mi. by rail; dried to 0.1% moisture.

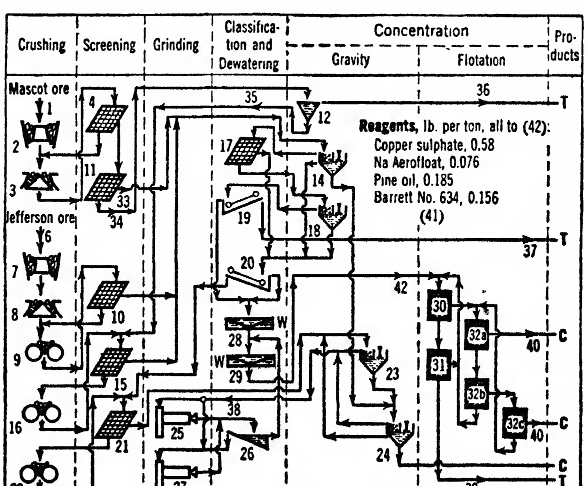

FIG. 102. AMERICAN ZINC CO. OF TENNESSEE.

Legend for Fig. 102:

1. At mine, 40-ton surge bin in head frame; Ross chain feeder; 1 @ 48-in. belt conveyor; 80% of total mill feed.
2. 1 @ 30-in. gyratory, 3 1/2-in. set, 147 r.p.m., 55 hp. actual, 75-hp. motor.
3. 1 @ 4-ft. cone crusher, 1 3/4-in. set.

37. 15% of Mascot mine feed.
38. 30% of Mascot mine feed.
39. 35% of Mascot mine feed; 0.1% Zn.
40. 97% recovery on flotation feed.
41. Further small additions of pine oil and Aerofloat to rougher cell No. 2; of Aerofloat and $CuSO_4$ to rougher cell No. 6, and of pine oil and Aerofloat to the first cleaner cell.
42. 3 Janney-cell agitators in series, 600 r.p.m., 2-min. time-factor, 40% solids, *p*H 8.4.

Summary. Three-stage crushing to <1 1/4-in. 1 1/4~3/8-in. roughed in sink-float cone with discard of 49% as tailing assaying 0.4% zinc. Sink concentrate crushed through 1/2-in. in one-stage closed-circuit rolls. All <1/2-in. material jigged in a rougher-cleaner circuit with recrushing of coarse middling to 3-m.; 15% discarded as tailing. Jig middling reground to 35 *mog* and floated, with 2 cleanings of concentrate.

This plant is unique in that the relatively coarse and extremely nonuniform dissemination of the sphalerite causes a comparatively low grade tailing to be freed at 1 1/2-in. size, while an active local market for crushed limestone yields a credit against values discarded in coarse tailing that turns such discard into profit.

Wisconsin-Illinois zinc deposits are small and scattered both geographically and in ownership. Central milling of crude ore has not developed. Hence the mills are, of necessity, small and crude. The practice of the district is to erect a small mill at the pit mouth, rough the ore by gravity concentration, in most cases on one or two jigs, and sell concentrate to central cleaning mills. In the past these have been roasting-magnetic mills such as the mill of the NATIONAL SEPARATING CO. (Fig. 105). The VINEGAR HILL ZINC CO.

has built a flotation plant to treat its own and custom rough concentrate, but the present roasting plants are not fitted to handle large tonnages of fine concentrate, so, despite that sulphuric acid is one of the profitable products, marcasite concentrate is not salable.

One-jig mills. Fig. 103 (*95 J 785; 59 A 117*).

Ore: Galena, sphalerite, marcasite, and pyrite in gangue of dolomite, calcite, and barite.
Capacity: 100 to 150 tons per 10 hr.
General: This type of mill is applicable only to low-grade coarsely disseminated ores having a high iron-zinc ratio and not much lead. With such ores much of the lead is recovered in a salable concentrate, and from 60 to 80% of the zinc in a zinc-iron concentrate assaying 20 to 40 or 45% Zn. This

3. 1 @ 24-in. rolls.
4. 1 @ 14-in. bucket elevator.
5. 1 @ 3×6-ft. trommel, 0.5-in. opening.
6. 1 @ 24-in. rolls.
7. 1 @ 30×36-in. 7- to 9-cell Cooley-type jig, 200 r.p.m.; concentrate drawn continuously from hutches and shoveled from sieves at the discretion of the operator.
8. Desliming box; sand to an elevator to tailing pile (Sec. 20, Art. 3); slime to pond.
9. To a custom mill, *e.g.*, Fig. 104, flotation section; or Fig. 105.

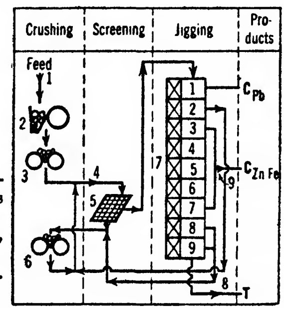

FIG. 103. One-jig zinc mill.

product is sold to the plants with magnetic separators. (See NATIONAL ZINC SEPARATING CO., Fig. 105.) If lead content of feed is relatively high, too much lead goes into the zinc concentrate and a 2-jig mill (p. 162) must be used.

Dodgeville Mining Co. Fig. 104 (*Tref 9/42*).

Location: Dodgeville, Wis.
Ore: Galena, sphalerite, marcasite, and pyrite in a gangue of dolomite, calcite, and barite.
Capacity: 190 tons per 24 hr.
Assays: See Table 73.
Recovery: See Table 73.
Ratio of concentration: Gravity lead, 160 : 1; flotation lead, 56 : 1; zinc, 3 : 1.
Power: Purchased; 3-phase, 60-cycle, 220-volt.
Water: From mine.

Legend for Fig. 104:

18. 1 @ 8-cell No. 12 Denver Sub-A machine; *a* = cells 2 to 8, *b* = cell 1.
19. 1-in. Denver vertical sand pump; 8-ft. dewatering cone; 4×2-ft. drum filter; cake 6% water.
20. 25% solids.

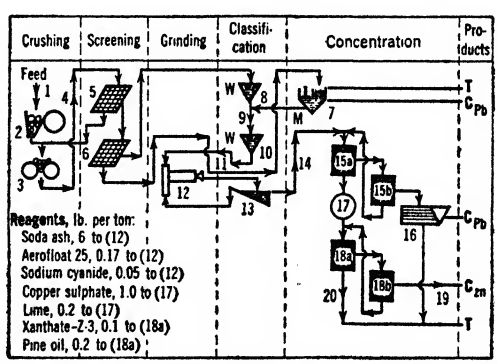

FIG. 104. DODGEVILLE MINING CO.

Table 73. Assays and recoveries at Dodgeville Mining Co.

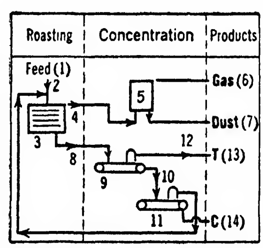
Material	Tons per 24 hr.	Assays, %		Distribution, %	
		Pb	Zn	Pb	Zn
Feed	192	0.93	4.5	100.0	100.0
Jig lead conc	1.2	75.0	2.0	50.5	0.3
Jig middling (flotation feed)	38.4	1.50	20.1	32.4	89.1
Jig tailing	152.4	0.20	0.6	17.1	10.6
Flotation lead conc	0.7	75.0	2.0	29.3	0.2
Lead concentrate, combined	1.9	75.0	2.0	79.8	0.5
Flotation zinc conc	12.3	0.4	61.5	....	88.1
Flotation tailing	25.4	Tr.	0.5	3.1	0.8
Tailing, total	177.8	0.2	0.58	20.2	11.4

Summary. Two-stage crushing to $^5/_8$-in.; jigging of $^5/_8\sim{}^1/_{16}$-in. feed to make finished lead concentrate, tailing, and a lead-zinc middling; grinding middling to 28 *mog* and differential floating by rougher-cleaner flows in both lead and zinc circuits with lead concentrate run up in grade by tabling.

Two-jig mill. VINEGAR HILL ZINC CO. has a typical 2-jig mill at Platteville, Wis., comprising 2-stage primary crushing in jaw crusher and closed-circuit rolls to about $^1/_2$-in.; desliming and rough jigging the deslimed material to discard tailing, returning middling to the primary-crushing circuit, and sending rough concentrate to a secondary closed rolls circuit, the product of which is rejigged, making finished lead concentrate, a middling circulated through the grinding circuit, and a rough zinc concentrate which is sent to a custom flotation plant. Slimes are tabled to make lead concentrate, tailing, and middling to flotation. Recovery is about 90% Pb and 80% zinc. Cost, about 35¢ (1941).

National Zinc Separating Co. Fig. 105 (*107 J 1107*).

Location: Cuba City, Wis.
Ore: Zinc-iron concentrate from Wisconsin district zinc mills.
Capacity: 275 tons per 24 hr.
Assays, % Zn: Feed, 20 to 45; concentrate, 59 to 61.5; tailing, 4 to 5.
Costs: Roasting and separating, $1.28; Cottrell precipitator, $0.18; receiving and shipping, $0.91; general, $0.63; total, $3 per ton of roaster feed.



Legend for Fig. 105:

1. Gravity concentrates from neighboring plants.
2. Sampler; bin with separate compartments for concentrates from different mines.
3. 22 $^1/_2$-ft. diameter roaster, 1 drying hearth and 7 for roasting. No fuel added. Maximum temperature at seventh hearth, 900° to 1,000° F. Surface of marcasite oxidized to Fe_3O_4. Decrepitation during roasting (see Table 74) causes a decrease in CaO content through dusting. LINDEN ZINC Co., Linden, Wis., and WISCONSIN ZINC Co., Cuba City, Wis., use an oil-fired rotary kiln on the ground that the degree of roasting can be better regulated.
4. Gas.
5. Cottrell precipitator. 2 units, can be operated together, but ordinarily operated separately and alternately for 2-week periods. Feed about 9,000 cu. ft. of gas per min. at 290° F.; velocity, 6 f.p.s. 36 collecting electrodes in each unit, made of 12-in. 14-gage steel pipe 15 ft. long.
6. 4 to 5% SO_2.
7. About 95 to 97% of total roasting loss. Comprises about 1.6% of solid feed to furnace.
8. 4 @ 2×26-ft. rotary cooling drums. 6 r.p.m. Shells $^5/_{16}$ in. riveted steel plate. Water-cooled by outside spray. 30 gal. water per min. per machine. Ore not completely cooled, as it is not then so magnetic as when slightly warm to the hand.
9. Dings MM-type magnetic separators. Campbell, Wetherill & Knowles magnets used in other plants in district. First poles draw 2 amp. at 225 volts; second, 3 amp. at 225 volts. Air gap of secondary magnets to shaking tray, $^3/_8$ to $^1/_2$ in. Capacity, 60 tons per 24 hr.
10. 56 to 58% Zn and 4 to 5% Fe.
11. Dings-type HI magnetic separator. 2 @ 12-in. feed belts, 70 f.p.m. 4 magnets in series drawing 7 $^1/_2$ to 15 amp. Capacity, 40 to 45 tons per 24 hr.

Table 74. Screen analyses of feed and product of zinc-concentrate roaster

Size	Weight, per cent.	
	Feed	Product
0.25-in.	0.20	0.10
0.12	21.70	9.70
10-m.	17.90	7.80
20	28.10	23.30
40	22.90	29.10
<40	9.20	30.00

FIG. 105. NATIONAL ZINC SEPARATING CO.

Legend for Fig. 105—Continued:

12. Belt conveyor; elevator; storage bin; sulphuric-acid plant.
13. Magnetic product. Averages 25% S and 4 to 5% Zn.
14. 61.5% Zn.

Summary. Roasting and magnetic separation.

Zinc carbonate ores are relatively rare.

In the Highland, Wis., district (*99 J 906*) small deposits of mixed carbonate and sulphide ore are worked by leasers. The ore is hand-picked and the high-grade material stacked on the surface until sufficient has accumulated or until weather conditions are suitable and is then crushed in a set of slow-speed rolls, roughly concentrated in a log washer and cleaned on a power hand jig. The mixed concentrate carries about 40% Zn. Recovery is, naturally, low, but the deposits are too small to warrant more elaborate equipment. At MONTEPONI, Sardinia (*83 J 1094*), a 500-ton plant treating calamine in dolomite with some zinc, lead, and iron sulphides consists of a 4-in. grizzly and a series of shaking screens of 1.25-, 0.8-, 0.55-, 0.4-, 0.28-, 0.2-, 0.12-, and 0.08-in. apertures to prepare feed for a picking belt and a series of jigs. Concentrate and tailing are rejected at all sizes and middling is reground and treated by magnetic separation to remove iron.

New Jersey Zinc Co. Fig. 106 (*Q* by J. S. Pellett, Mill Sup't).

Location: Franklin, N. J.
Ore: Willemite, franklinite, and zincite in calcite gangue.
Capacity: 1,640 tons per 24 hr.
Assays, % Zn: feed, 20; concentrate: magnetic (franklinite), 17; gravity (willemite-zincite), 47; tailing, 1.25.
Recovery: 98%.
Labor: American, Hungarian. Tons per man-shift: operating, 11.5; repairs, 31.4.
Running time: 94%. Loss due to repairs and feed delays.
Water: Comes 1/8 mi. by gravity from river. About 99% re-used. Net consumption is 1/6 ton per ton of ore.
Building: Old buildings are frame; new are steel and concrete. Concrete floor in wet parts, slope 1/4 in. per ft. Some of buildings heated. Site, part level and part sloping.
Machinery handling: Chain blocks and cranes.
Power: Company steam-power plant. Motors, 440-volt, 60-cycle. CONSUMPTION, 18.7 hp-hr. per ton milled.
Transportation: Ore skips discharge into crusher bins. Main-line railroad at plant. Concentrate, 90 mi. by rail to smelter.
Tailing sent by rail to mine for fill.

Legend for Fig. 106:

1 Ore, about 12-in. max., hoisted into headframe in 5-ton skips.
2. Grizzly, 3-in. spaces.
3. Steel hopper with roll feeder.
4. 3×6-ft. wash trommel, 2-in. square openings.
5. Horizontal revolving annulus, serving as a picking table. 2 men remove steel, wood, rope, etc., and some waste rock which is returned as mine fill.
6. 8-K Gates gyratory, 3-in. open setting. A duplicate is in parallel as a spare.
7. Scraper dewaterer.

121. 1 @ 6-ft. cone.

a Sec. 11, Table 29.

Summary. Graded crushing dry from <12-in. to <1/2-in. fine-roll feed n four stages comprising a gyratory and three Edison rolls in series, with circuit closed on the last pair of rolls. Nominal maximum-size reduction ratio on the gyratory is 4 and on the rolls 2. Fine crushing dry to 0.1-in. magnetic-separator feed size in one stage by rolls in closed-circuit with screens, with a final set of rolls to recrush oversize on rescreening. Washing to recover rich slime and clean sands for concentration. Concentration by magnetic separation of six closely sized feeds below 0.1-in., with return of separator middling to regrind rolls; jigging of coarse separator tailing at the same close sizes treated on the separators; and tabling of the fine separator tailing after close hydraulic classification.

This flowsheet is unique, adapted for the treatment of a unique, rich ore which contains three zinc minerals of markedly different zinc content (franklinite, 25.8% Zn; willemite, 41.4; zincite, 80.2). While it would be possible to concentrate the franklinite on jigs and tables, to do so would seriously lower the grade of the gravity concentrate and likewise destroy the iron-free smelter feed that the gravity concentrate now constitutes. The dusts and slimes taken for concentrate assay substantially the same as the feed (20% Zn).

Halkyn District United Mines, Ltd. Fig. 107 (*46 IMM 339; 48 IMM 691*).

Location: Halkyn, North Wales.
Ore: Galena, cerussite (up to 25% of total Pb) and sphalerite in calcite, limestone, and shale.
Capacity: 400 tons per 24 hr.

Legend for Fig. 107:

Assays and recoveries: See Table 75.
Power: 22 hp-hr. per ton.
Labor: 8.5 tons per man-shift.
Costs, ¢ per ton of original feed: Crushing, 8.6; sink-float, 16.8; jigging, 3.2; tabling, 3.0; grinding, 4.6; flotation, 10.4; miscellaneous, 36.2; total, 82.8. (This covers a break-in period.)

Table 75. Assays and recoveries at Halkyn

Material	Assay, %		Distribution, %	
	Pb	Zn	Pb	Zn
Feed	12.46	2.21	100.0	100.0
Jig conc.	81.20	2.00	30.6	4.2
Table concentrate	80.42	2.81	46.2	9.1
Flotation lead conc.	77.95	5.72	20.4	8.4
Total lead conc	80.12	3.18	97.2	21.8
Zinc conc. (flotation)	4.04	62.56	0.8	67.7
Sink-float tailing	0.07	0.13	0.3	3.5
Flotation tailing	0.79	0.56	1.7	7.0
Total tailing	0.33	0.28	2.0	10.5

Summary. Two-stage crushing to 1-in.; washing to remove <2.5-mm. material; sink-float treatment of >2.5-mm. with rejection of 55% of mill feed as tailing; classification and tabling of <2.5 mm. primary feed, making finished concentrate; crushing and jigging of sink-float concentrate; regrind and flotation of jig and table middling.

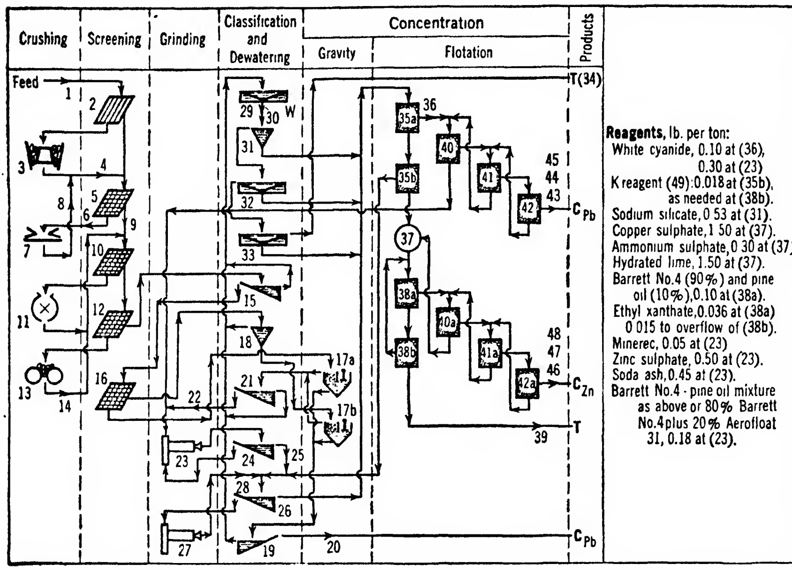
Bunker Hill & Sullivan Mining & Concentrating Co., West mill. Fig. 108 (*Q* by R. S. Handy; *140 ✠8 J 53*).

Location: Kellogg, Idaho.
Ore: Approximate composition: Galena, 10%; marmatite + some sphalerite, 8%; pyrite + siderite, 36%; quartzite, 46%; Ag, 4 oz. per ton; small amounts of tetrahedrite and chalcopyrite.
Capacity: 1,200 tons per 24 hr.
Assays: See Table 76.
Recovery: See Table 76.

Table 76. Metallurgical results, Bunker Hill & Sullivan Mining & Concentrating Co.

Material	Per cent.				Oz. per ton
	Pb	Zn	Fe	Insol.	Ag
Feed	8.6	5.0			3.6
Lead conc	60	5.5	11	1.5	25
Zinc conc	2	51.5	7	3.8	2
Tailing	0.74	0.90	15	61	
Recovery, %	90	77.7			91.5

Ratio of concentration: 5 : 1.
Labor: American. Tons per man-shift: operating, 50; repairs, 157.
Water: By gravity pipe line 3.5 mi. from springs; CONSUMPTION, 3.6 tons per ton milled; about 50% re-used.
Building: Wood; sloping site. Wood floors slope 0.1 in. per ft., which is found to be satisfactory. Steam heat.
Machinery handling: Chain blocks and air hoist.
Power: Purchased. Transmitted 80 mi. at 110,000 primary and 2,300 secondary voltage. Motors, 2,300-volt, 60-cycle for 25-hp. and over; 440- and 220-volt for smaller. CONSUMPTION, 24 hp-hr. per ton of ore milled.
Running time: 96%. One day per month set aside for oiling and repairs.
Transportation: Railroad at concentrator. Feed, 1/4 mi. in mine cars by electric locomotive; concentrate, 1 mi. to smelter.
Tailing: Pumped to settling dam, overflow to river.



Legend for Fig. 108:

Tailing	11.0	22.7	18.5	8.5	4.2	25.5	15.0	22.9
Third cleaner:								
Conc.	56.7	6.9	11.0	1.5	2.3	52.5	7.3	3.8
Tailing	12.1	22.9	18.1	9.4	3.3	31.5	14.6	15.9

<35-m. "decolloided" primary classifier overflow, and regrinding primary lead middling before return to the head of the roughing circuit; triple cleaning of both rougher concentrates.

The principle of this flowsheet is to scalp out all galena freed by crushing to 1/4-in., together with that further amount freed by grinding the scalped sands to 35-m., confining fine grinding to the locked middling lifted in the lead-flotation circuit. Such treatment is, of course, possible only when the mineral is relatively coarsely disseminated. Removal of the finest primary slime (DECOLLOIDING) is asserted to improve both recovery and grade of concentrate. By comparison with BROKEN HILL SOUTH (Fig. 109), the relatively low grades of final flotation concentrates and low recoveries are hard to understand; they are not impossibly due to the coal-tar oil added at the grinding mill, which should have the effect of making a tough froth, hard to clean.

Broken Hill South, Ltd. Fig. 109 (T. A. Read, Chief Metallurgist, *88 Aa 247; 98 Aa 305*).

Location: Broken Hill, New South Wales.
Ore: Galena and blende in quartz, quartzite, feldspar, chlorite, calcite, and rhodonite.
Capacity: 1,300 tons per 24 hr.
Assays: See Tables 78, 80, and 81.

Table 78. Assays at Broken Hill South

Material	Percentages			
	Feed	Gravity concentrate	Flotation concentrate	
			Lead	Zinc
Insol.	....	2.30	1.02	....

17. 6 Butchart tables, Sec. 11, Table 60.

18. 1/2 duplex drag-belt classifier, 40-sq. ft. basin, 56-in. overflow, 4-in. per ft. slope, 2 @ 14-in. belts with 3×20-in. scrapers spaced 6 in., 58.5 f.p.m.

19. 1/2 @ 5×10-ft. tube mill, feed 29 tons per hr. 19% >40-m.; product, 7.5% >40-m.

20. 3 @ 4×19 2/3-ft. simplex rake classifiers for entire mill; 33 tons per hr.

21. 6 @ 25×10-ft. thickeners, 1,000 to 1,200 gal. per min. feed pulp, sp. gr. 1.063.

22 1 @ 12×3.5-ft. conditioner, 8 1/2 r.p.m., 6-hp. motor; entire mill stream joined here; sp. gr. 1.48 to 1.65.

23. 2 @ 12 cell South-mine subaeration machines, (*a*) first 7 cells, *p*H feed = 7.9; (*b*) 3 cells making middling; 2 spares. This is a 24-in. M-S subaeration cell with a shrouded Cunningham impeller (see Sec. 12, Art. 29) 19-in. diam., 1,442 f.p.m. 24.6 cu. ft. free air per min. per cell. Feed pulp sp. gr. = 1.5; power consumption, 4.75 hp. per impeller, 0.75 hp. per cell for air. See Table 80. Treatment time, 40 to 48 min. Sizing-assay test, see Table 81.

24. 3 @ 12-cell subaeration machines; (*a*) first 7 cells, *p*H feed = 8.3; (*b*) 3 cells making middling, 2 spares. 30.5 cu. ft. free air per min. per cell; time, 27 to 29 min.; total power per cell, 4.4 hp. For sizing-assay test see Table 81.

25. 1 @ 4-cell subaeration machine preceded by 1 agitation. Treatment time, 9 min. 34.6 cu. ft. free air per min. per cell; power consumption, 5.5 hp. total per cell.

26. 1 @ 6-cell subaeration machine; (*a*) 5 cells on concentrate, (*b*) 1 on froth middling. See Tables 80 and 81. Treatment time, 78 to 108 min. Power consumption, 3.5 hp. total per cell; air, 27.8 cu. ft. free air per min. per cell.

27. 1 @ 12-cell subaeration machine, only 10 cells active. 28.2 cu. ft. free air per min. per cell; total power per cell, 3.8 hp.; time, 30 to 40 min. For sizing-assay test see Table 81.

28. 20-ft. thickener; 4-leaf 6-ft. American filter.

29. Drag classifier; 2 @ 25-ft. thickeners; 1 @ 8-leaf 6-ft. American filter.

30. Drag classifier making sand for mine fill; overflow to slime pond.

31. 1 duplex and 1 quadruplex diaphragm pump, 51 s.p.m.

32. 2 @ 8×16-in.×47-ft. belt-bucket elevators.

Table 80. Assays of flotation products at Broken Hill South

Material *a*	Assays			Quantities		Solids, %

a Numbers in parentheses refer to flowsheet items.

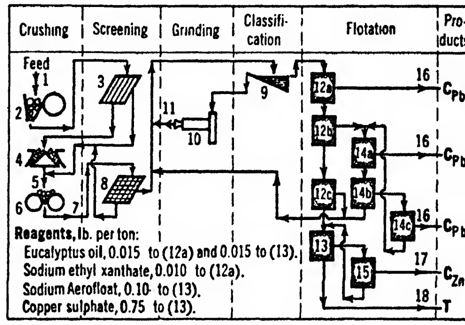
Summary. Three-stage crushing from run-of-mine to 4-mm. Jigging and tabling for granular lead concentrate with regrind of jig tailing for tabling. Table tailing reground in one stage, open-circuit, and the sand scavenged by flotation for lead middling, which is returned to the primary grinding circuit. Slime from gravity circuits is floated for lead at 65-m.; all lead-flotation tailing (slime and scavenger sand) at <35-m. is floated for zinc. One cleaning in both circuits with cleaner tailing returned to the head of the respective rougher circuits.

The relatively high lead and zinc tailing is accepted because of the economic advantages for exceptionally high grade lead concentrate, of granular zinc concentrate, and the fact that a granular tailing is useful for required mine-fill material, which otherwise would have to be quarried. Gravity concentration is used because of the presence of a certain amount of cerussite and highly friable partially oxidized galena, which factors lower recovery in all-flotation treatment. It is economically possible because of coarse dissemination of both sulphides.

Substantially the same flowsheet is used at North Broken Hill, working on a similar ore, and approximately the same results are achieved.

Zinc Corporation, Ltd. Fig. 110 (Staff, *Tref 2/39; 32 CEMR 27*).

Location: Broken Hill, N. S. W., Australia.
Ore: Galena and sphalerite in rhodonite, garnet, quartz, calcite, and fluorite.
Assays: Feed: 15.5% Pb, 4 oz. Ag, 10% Zn; lead concentrate: 77% Pb, 17 oz. Ag, 3.6% Zn; zinc concentrate, 53.5% Zn, 0.8 oz. Ag, 1.2% Pb; tailing: 0.55% Pb, 0.2 oz. Ag, 1.1% Zn.
Recovery: 96.6% Pb; 93.0% Ag; 86% Zn.



Legend for Fig. 110:

1. 7-ton automatic skips; 250-ton bin; chain feeder.
2. 1 @ 36×48-in. jaw crusher, 9-in. set.
3. 1 @ 15-ft. vibrating feeder, last 4 ft. a grizzly with 1 1/2-in. spacing; suspended magnet.
4. 1 @ 5 1/2-ft. standard cone crusher, 1 1/4-in. set.
5. 1 @ 30-in. conveyor, 250 f.p.m.; 1 @ 30-in. conveyor with traveling tripper, 250 r.p.m.; 3 @ 1,200-ton bins; 6 @ 18-in.×5-ft. vibrating feeders; 3 @ 18-in. belt conveyors with weightometers.
6. 3 @ 36×18-in. gear-driven Cornish rolls, 17 r.p.m.
7. 3 elevators.
8. 3 @ 4×5-ft. electric vibrating screens, 3-mm. aperture.
9. 3 @ 6×25 1/2-ft. rake classifiers, 2 3/8-in. slope per ft.; overflow 50% solids, 50% <200-m.
10. 3 @ 8×6-ft. ball mills, 22 r.p.m., 2 3/8-in. hard-iron balls.
11. 3 @ 14-in. pipe conveyors.
12. 3 @ 12-cell No. 21 Denver Sub-A flotation machines in parallel; *a* = cells 1 to 5, *b* = cells 6 to 8, *c* = cells 9 to 12.
13. 3 @ 12-cell No. 21 Denver Sub-A flotation machines in parallel.
14. 1 @ 4-cell No. 21 Denver Sub-A flotation machine; *a* = cell 2, *b* = cells 3, 4; *c* = cell 1.
15. 1 @ 8-cell No. 21 Denver Sub-A flotation machine.
16. 2 agitator-type surge tanks, 2 @ 6-leaf 6-ft. disk filters delivering cake (5.7% moisture) to railway cars.
17. 1 agitator-type surge tank, 2 @ 6-leaf 6-ft. disk filters discharging cake (7.7% moisture) to railway cars.
18. 2 rake classifiers, sand to 36-in. slow-moving drainage belt (to 19% moisture) and conveyor to storage for mine fill; overflow to thickeners and thence to slime pond.

FIG. 110. ZINC CORP.

Summary. Three-stage crushing to 3-mm.; one-stage closed-circuit grinding to 48-m.; differential all-flotation concentration with two-stage cleaning for lead and one for zinc.

This is the third of the large plants at Broken Hill; it departs from the North and South plant practices by omitting gravity concentration, making a slightly finer grind before flotation. Results are definitely better than at the other plants.

Cía. Industrial "El Potosí," S. A. Fig. 111 (*Q* by C. A. Mehring, Mill Sup't; *IC 6706*).

Location: Chihuahua, Chihuahua, Mex.
Ore: Approximate composition: Ag, 8 oz. per ton, Pb, 10.5%; Zn, 10%; Fe, 30%; CaO, 9%; insol. 5%. Principal minerals are galena, marmatite, pyrrhotite, and pyrite with minor amounts of limestone and silicates.
Capacity: 2,900 tons per 24 hr.
Assays: See Table 82.

Table 82. Assays of products at El Potosí

Material	Percentages					Oz. per ton
	Pb	Zn	Fe	S	Insol.	Ag
Feed......	10.5	10	30	....	5	8
Lead conc..	65.15	3.95	9.0	17.4	1.2	46.34
Zinc conc..	....	48.0	....	....	....	....
Tailing....	0.17	1.99	....	....	....	0.60

Recovery: Ag, 92.3%; Pb, 98.2%; Zn, 80.2%.
Ratio of concentration: Pb, 6.39 : 1; Zn, 6.05 : 1.
Labor: Mexican and foreign. Tons per man-shift, total, 22.35; percentage distribution of labor: foreman, 2.7; crushing, 5.5; grinding and classification, 8.2; flotation, 5.5; sampling, 2.7; filtering, 10.9; miscellaneous, 64.5.
Running time: 98.9%. Principal causes of loss: grinding mills and classifiers; power interruptions.

Water: Pumped 9 mi. from wells through 8-in. line against a total head of 450 lb. at 9.5 kw-hr. per 1,000 gal.; 43.1% reclaimed. Net CONSUMPTION, 1.12 tons per ton of ore.

Building: Steel, concrete floors sloping 3/8 in. per ft. in wet parts. Unheated. Sloping site.

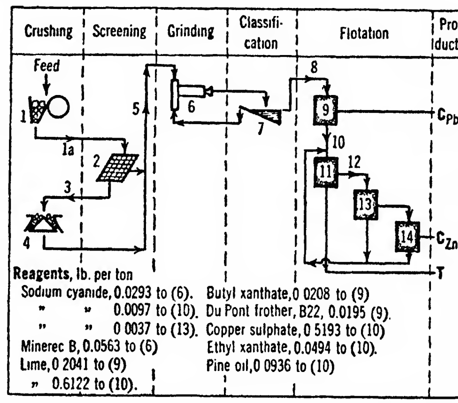
Machinery handling: 10-ton hand crane in coarse crushing; 20-ton hand and 8-ton electric cranes in grinding; 10-ton electric in concentration.

Power: Purchased. Comes 90 mi. at 110,000 volts. Motors, 2,200- and 450-volt. CONSUMPTION, 14.6 hp-hr. per ton milled. Percentage distribution: crushing and conveying to fine-ore bins, 3.6; grinding and classification, 40.3; flotation machines, 33.5; thickening, 4.1; sand pumps, 5.7; water pumping, 7.4; lighting, 2 7; assaying, 1.0; conveying in concentrator, 1.7.

Transport: Company railroad. Ore comes 6 mi. by electric train. Lead concentrate shipped by electric trams 8 mi. to A.S. & R. Co. smelter; zinc, 9 mi. to connecting rail, and thence to European smelters.

Tailing flows 1,000 ft. through a 12-in. launder to a 6-in. Wilfley pump which elevates and pumps it 500 ft. along one side of a tailing pond to a second 6-in. pump which elevates and pumps 1,225 ft. along the other side of the pond to a third 6-in. pump which elevates and pumps 1,100 ft. along the face of the dam. Pulp is bled off from the pump lines to build the dam walls.

Costs (July, 1932): Crushing, $0.017; grinding, 0.157; flotation, 0.189; concentrate handling, 0.029; water, 0.026; tailing disposal, 0.011; other expense, 0.075; total $0.504.



Legend for Fig. 111:

1. 36×24-in. jaw crusher at mine.

1a. In order: Electric railroad, 6 mi.; 2 coarse-ore bins, 2,600 tons total capacity; 1 @ 18-in. and 1 @ 24-in. apron feeder; 1 @ 24-in. belt conveyor; 1 @ 24-in. inclined belt conveyor with Merrick weightometer and 24-in. Dings bipolar suspended magnet.

2. 1 @ 4×5-ft. Hum-mer screen, 1/2× 1-in. openings.

3. 24-in. belt conveyor.

4. 1 @ 5 1/2-ft. standard cone crusher, 3/8-in. set.

5. In order: 1 @ 24-in. belt conveyor, 1 @ 18-in. inclined-horizontal distributing belt conveyor, 1 @ 600-ton, 20(diam.)× 28-ft. and 1 @ 500-ton, 20(diam.)×23-ft. ore bin in parallel; 2 @ 18(diam.)×12-in. drum feeders in parallel (one on each bin), 1 @ 12-in. and 1 @ 14-in. belt conveyor in parallel (one from each bin), each with one Merrick weightometer; 1 @ 12-in. belt conveyor.

6. 6 rod mills in parallel, as follows: 4 @ 6× 12-ft. Cole-Bergman; 2 @ 5×12-ft. Marcy.

7. 4 @ 6×27-ft. heavy-duty rake classifiers. Each Marcy has an individual classifier, the Cole-Bergman mills have one classifier to two mills.

8. 1 @ 6-in. Wilfley sand pump; 1 @ 4-way revolving-tank distributor. 45% solids.

9. 4 @ 14-cell 18-in. M-S Subaeration flotation machines in parallel; 325 r.p.m., cast-iron impellers, life 100 da.; cast-iron liners, life 500 da.; air at 3-lb per sq. in., temperature according to season, 14-min. time-factor, 50% solids, *p*H 8.1.

10. 1 @ 4-in. Wilfley sand pump, 1 @ 4-way revolving-tank distributor.

11. 4 @ 3-cell 56-in. Fagergren machines (2 @ 12-cell 24-in. M-S standard machines in reserve). 500 r.p.m. Rubber-covered rotor, life 220 da.; rubber-covered stator, life 400 da. 5-min. time-factor. Rough concentrate, 43% Zn.

12. 1 @ 2-way splitter.

13. 1 @ 3 cell 56-in. Fagergren machine. 500 r.p.m. Rubber-covered rotor and stator, lives 350 and 550 da. respectively. 6-min. time-factor, 35% solids, *p*H 8.1. Concentrate, 47% Zn; tailing, 28% Zn.

14. 1 @ 3 cell 56-in. Fagergren machine. 6-min. time-factor, 35% solids, *p*H 8.1; tailing, 30% Zn.

FIG. 111. CÍA. INDUSTRIAL "EL POTOSÍ".

Summary. Crushing from run-of-mine to <1/2-in. rod-mill feed in two stages comprising a jaw crusher and a cone. Grinding to 22% >65-m. in one stage with rod mills in closed circuit. All-flotation differential concentration, in two stages on the primary pulp stream, making finished lead concentrate directly off the primary stream, while zinc concentrate is cleaned twice.

Compañía Minera de Peñoles, S. A. Fig. 112 (*Q* by Irving M. Symonds, Mill Sup't; *153 A 623*).

Location: Avalos, Zacatecas, Mex.

Ore: Pb, 8 to 14% as galena; Zn, 14 to 25% as sphalerite; Fe, 20 to 35% as pyrite; insol., 1 to 2%; limestone, balance; composite from company ores, ores from leased mines, and some custom ore. Dissemination coarse.

Capacity: 600 tons per 24 hr.

Assays: See Table 83.

Recovery: See Table 83.

Table 83. Assays and recoveries at Cía. Minera de Peñoles (1941)

Material	Assays				Recoveries, per cent.			
	Au, oz. per ton	Ag, oz. per ton	Pb, per cent.	Zn, per cent.	Au	Ag	Pb	Zn
Feed	0.013	7.15	7.6	17.3	100	100	100	100
Lead conc.	0.065	61.3	69.5	5.3	52.5	90.7	97.3	3.3
Zinc conc.	0.004	0.90	0.45	60.9	8.8	3.4	1.6	93.0
Tailing	0.008	0.67	0.14	1.03	38.7	5.9	1.1	3.7

Ratio of concentration: Pb, 6.5 : 1; Zn, 4.0 : 1.

Labor: Mexican. Tons per man-shift: operating, 6.5; repairs, 2.8.

Running time: 90%; principal cause of loss is general repairs.

Water pumped 2.7 mi.; 10 hp. installed; pump run 8 to 12 hr. per day. CONSUMPTION: 2.5 tons per ton milled. None reclaimed.

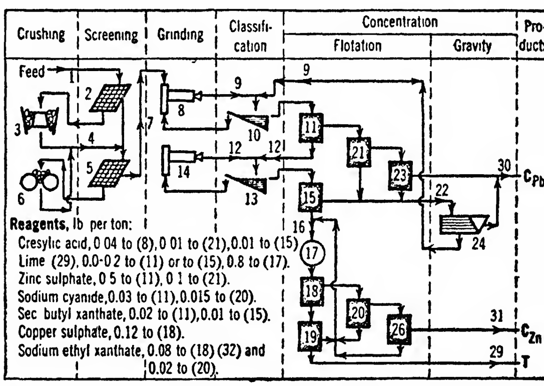
Building: Steel and wood on a slightly sloping site; concrete floors slope 1/2 in. per ft. in wet part; unheated.

Machinery handling by chain blocks throughout.

Power: Generated at plant at 2,300 volts; motors, 440-volt, 60-cycle. CONSUMPTION (Aug. 1941): Crushing, 1.2; grinding and classifying, 9.6; concentration, 9.0; concentrate dewatering, 1.6; tailing disposal, 1.4; miscellaneous, 1.3; total, 24.3 hp.

Transport: Aerial tram from mine to mill; lead concentrate 125 mi. by rail to smelter; zinc concentrate to United States.

Tailing: Pumped to tailing dam built by discharge from pipe at 6-ft. intervals around face, with manual shaping.



Legend for Fig. 112:

1. <3-in. product to 7 cable-station ore bins (capacity 500 tons); 26-in. belt conveyor with 30-in. Dings magnetic head pulley.

2. 4-ft. type 33 Hum-mer screen, 5/8-in. sq. aperture.

3. 6-in. gyratory set to crush to <7/8-in. Capacity 200 to 250 tons per shift, according to moisture content.

4. 18-in. belt conveyor; 12-in. bucket elevator.

5. 4-ft. type 33 Hum-mer with two vibrators, 3/8-in. sq. aperture. Finer crushing would be desirable from the standpoint of grinding.

6. 30×14-in. A-C rolls.

7. Automatic sampler; 16-in. belt conveyor; 6 fine-ore bins (capacity 375 tons live; lack of storage here makes blending inadequate and feed assay varies greatly); 6 belt feeders; 18-in. belt conveyor.

8. 1 @ 5×10-ft. Marcy rod mill, 21 r.p.m. Discharge opening closed to 12-in. diam. 2 1/2-in. carbon-steel rods. Manganese-steel liners, life 550 to 600 da. on shell and feed end, 200 to 300 da. at discharge end; 0.11 lb. total per ton, cost 1.5¢ per ton.

9. 4-in. Wilfley pump.

10. 4 1/2-ft. light-duty rake classifier, 24 s.p.m. Overflow, 21% >65-m., 36% <200-m. Sands drawn in large part (85 to 90%) from 14 or 16 @ 1-in. pipes through bottom under rakes, at 80% solids.

11. 1 @ 8-cell 18-in. M-S special subaeration machine (Fig. 112*A*). *p*H at head, 7.9 to 8.2. Temp. varies between 50 and 75° F. 46% solids.

12. 4-in. Wilfley pump.

13. 6-ft. rake classifier, 22 s.p.m.

14. 5×8-ft. Marcy ball mill, 12-in. discharge opening 27 r.p.m. 2-in. cast-iron balls. Manganese-steel liners, 0.10 lb. per ton.

15. 8-cell M-S subaeration machine (Fig. 112*A*).

16. 3-in. Wilfley pump.

17. 8×12-ft. conditioning tank.

FIG. 112. CÍA. MINERA DE PEÑOLES.

Legend for Fig. 112—Continued:

30. 5 1/3×6-ft. Oliver filter; tank overflow to 18-ft. Dorr thickener returning spigot product to filter. Cake to R.R. cars with about 5.3% water.

31. As (30).

32. 1/3 to 1/2 of this often added about half-way along cell.

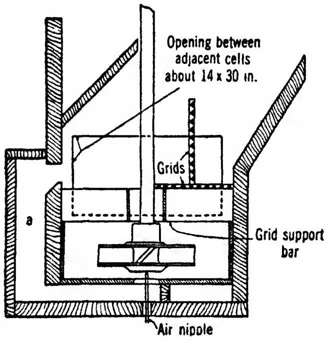

FIG. 112A. Hebbard-type subaeration machine at PEÑOLES.

Note to Fig. 112A. A Hebbard-type subaeration machine was modified by addition of the enclosed circulating launder *a*. Bottom of weir to launder is 16 in. above bottom liner. Tailing overflow weir is about one-half usual width. Thus modified, the cell does not choke. Air-lift machines were entirely unsatisfactory with the heavy sulphide ore treated here; they clogged badly and produced high-assay tailing.

Summary. Three-stage crushing from run-of-mine to <3/8-in., the last stage in closed circuit with a screen. Concentration essentially all-flotation with rougher-scavenger flow on the primary run for both lead and zinc, and one cleaning of primary rougher concentrate. A table is used on once-floated lead middling (cleaner tailing and scavenger froths) to remove difficultly floatable lead mineral before recirculation to the grinding mill.

Pend Oreille Mines & Metals Co. Fig. 113 (*141 #3 J 29*).

Location: Metaline Falls, Wash.

Ore: Coarsely disseminated galena-sphalerite (substantially free at 48-m.) in quartz-dolomite gangue, with some pyrite.

Capacity: 750 to 850 tons per 24 hr.

Assays: Feed: 1.65% Pb; Zn, 4.46%; Fe, 0.6%. Concentrate and tailing, see Table 84.

Recovery: See Table 84.

25. 2-in. United Iron Works pump; 1 @ 20-ft. thickener with 3-in. diaphragm pump; 4-disk American filter. Copper sulphate added ahead of the thickener as a coagulant.
26. 48 to 55% <200-m., according to dissemination of zinc. No reagents are needed at this point to depress zinc.
27. When feed is high in pyrite, sodium Aerofloat is substituted.
28. One-half added to the filter and the balance at the head of the rougher de-leader. About 4 to 5 lb. per ton of concentrate.

Table 84. Effects of de-leading operation at Pend Oreille

Product	Weight, per cent.	Assays, per cent.		Recovery, per cent.	
		Pb	Zn	Pb	Zn
WITHOUT DE-LEADING: *a*					
Lead conc.	1.86	81.82	0.38	92.1	0.2
Zinc conc.	6.56	2.00	62.27	7.9	91.6
Plant tailing	91.58	*b* 0.18	0.40	......	8.2
WITH DE-LEADING:					
Lead conc.	1.86	81.82	0.38	92.1	0.2
De-leading float	0.19	60.00	9.53	6.8	0.4
Total lead conc.	2.05	80.00	1.27	98.9	0.6
De-leaded zinc	6.37	0.31	63.81	1.1	91.2
Plant tailing	91.58	......	0.40	......	8.2

a Taking finished zinc concentrate from Cell *21* (see flowsheet).
b Including loss in zinc concentrate.

Summary. Two-stage crushing to <1/2-in.; second stage in closed circuit. One-stage closed-circuit primary grind with regrind of zinc primary-cleaner tailing. All-flotation differential concentration comprising 3-stage rougher-scavenger, flow for lead, with 2-step cleaning; and for zinc 7-stage roughing and scavenging, with 3-stage middling counterflows, and 3-step primary cleaning followed by 2-step de-leading of zinc concentrate.

De-leading was developed at this plant to decrease the lead content (2%) of the thrice-cleaned zinc concentrate. This lead comprised substantially 8% of the total lead in the ore, and was penalized when in excess of 1.5% in zinc concentrate. The lead is fine, free, but slow-floating, and would not come up in the lead circuit either with increase in conditioning or flotation time or with any allowable reagent manipulation; neither was it found possible to depress it from zinc concentrate. The principal operating difficulty lay in uncontrollable frothing; the addition of half of the cyanide necessary for zinc depression before filtration was the solution of this difficulty. For performance see Table 84. The lead float is 2.8% of the feed to de-leading; substantially 80% of the lead in the de-leaded zinc is in the <200-m. slime. Economic benefits (Oct. 1939) were an increase of $0.07 per ton of feed from additional lead recovery (6.8%) despite a drop (81.8 to 80.0) in grade of lead concentrate, and $0.09 per ton from higher grade of zinc concentrate (63.8 *vs.* 62.3) despite a drop (91.6 to 91.2) in zinc recovery. Increased cost was $0.06 per ton of feed.

This flowsheet represents the ultimate yet reached in point of grade of concentrate and recovery; the cost analysis presented indicates definite economic advantage under the smelter contracts prevailing.

Trepca Mines, Ltd., at Zvecan, Yugoslavia (*17 MMt 584*), treats 1,800 to 2,000 metric tons of ore per 24 hr. by 3-stage crushing to 1/4-in. in jaw crusher, standard cone and short-head cone, with scalping screens ahead of the first two stages and a closing screen on the final stage; one-stage closed-circuit grinding, and differential flotation as in Fig. 114. Results in 1935 were as in Table 85.

Pyrite conc.	....	....	0.4	50.8	....	....	....	....

a Zinc mineral is marmatite assaying 54 to 55% Zn.

Lead and zinc concentrates were shipped *via* Salonika to western European smelters and pyrite *via* Danube to central Europe.

This plant, by reason of long concentrate hauls, is forced to make exceptionally high grade concentrate; it manages to do so and yet attain fair lead-silver and excellent zinc recoveries.

St. Joseph Lead Co., Edwards Division. Fig. 115 (*Q; IC 6574*).

Location: Edwards, N. Y.

Ore: Massive mixture of pyrite and sphalerite with some galena in gangue of calcite, dolomite, quartz, and other silicates. Sphalerite contains about 5% Fe. The ore is moderately hard.

Table 86. Assays at Edwards mill

Material	Assays, per cent.		
	Zn	Pb	Fe
Feed	8.25	1.05	12.45
Lead conc.	....	61.72	....
Zinc conc.	56.16	....	....
Iron conc.	....	....	41.58
Tailing	2.2	....	6.9

Capacity: 1,250 tons per 24 hr.

Assays: See Table 86.

Recovery: Zinc, 90.3%; Pb, 63.6%; Fe, 84.1%.

Ratios of concentration: Zn, 7.4; Pb, 90.8; Fe, 3.9.

Water pumped 4,000 ft. from a lake at an expenditure of 70 hp. to a 100,000-gal. storage tank above the mill; water CONSUMED, 2.9 tons per ton of ore; no recovery.

Power purchased; comes 15 mi. at 23,000 volts; motors, 2,300- and 220-volt, 60-cycle; motor-generator set for magnets and excitation of synchronous motors. CONSUMPTION, 24.5 hp-hr. per ton.

Labor: American. 34.5 tons per man-shift operating.

Running time: 99.64%; 6-day week. Loss due principally to repairs and power failures.

Building: Sloping site. Steel frame; enclosure, J-M insulation board and J-M corrugated Transite Cement floors; slope 1/4 in. per ft. in wet portion. Heated.

Machinery handling: Chain blocks on rails.

Tailing disposal: Pumped by 6-in. Wilfley pump 2,100 ft. through 8-in. wood-stave pipe.

Distances: Mine to mill, 500 ft. by conveyor; mill to smelter, 450 mi.; railroad at plant.

42. 1 sampler as in (40); sump; 1 @ 6-in. Wilfley pump, 900 r.p.m., 40-hp. motor (29 hp. actual).

Summary. Three-stage crushing from run-of-mine to <1/2-in.; two-stage grinding, the first an open-circuit rod mill, the second a closed-circuit ball mill; all-flotation three-mineral differential flotation with two-stage rougher-scavenger flow for each mineral, four cleanings for lead and two each for zinc and iron.

Zinc is the primary mineral at this plant; grade of concentrate must be kept high on account of long concentrate haul; recovery is creditable in view of this limitation and the relatively fine dispersion of the zinc-pyrite intergrowth.

Consolidated Mining & Smelting Co. of Canada, Ltd. Fig. 116 (*Q* by R. W. Diamond, Ass't Gen'l Sup't).

Location: Kimberley, B. C.

Ore, approximate composition: Percentages: PbS, 11.6; marmatite (FeS_8ZnS), 10.3; FeS_2, 4.0; Fe_7S_8, 55.6; SiO_2, 10.4; Al_2O_3, 3.1; CaO, 1.2; MgO, 1.3; MnO_2, 0.65. This is a heavy finely complex sulphide ore with small amounts of calcite and silicates; it is brittle and grinds readily to 100-m. but is difficult below this size.

Capacity: 6,500 tons per 24 hr.

Assays: See Table 87.

Table 87. Assays of products, Consolidated Mining & Smelting Co. of Canada

Material	Assays, %			Distribution, %		
	Pb	Zn	Fe	Pb	Zn	Fe
Feed..........	10.4	6.5	35.7	100.0	100.0	100.0
Lead conc.....	71.0	3.2	6.4	91.0	6.6	2.4
Zinc conc......	3.3	51.2	11.2	3.5	87.5	3.5
Tailing........	0.75	0.5	44.5	5.5	5.9	94.1

Recovery: Pb, 85%; Zn, 84.5%.

Ratio of concentration: 4 : 1 on total concentrate.

Labor: Mostly British. Tons per man-shift: operating, 24.9; repairs, 266.3.

Running time: 93%. Principal causes of loss are repairs and smelter requirements.

Water: Creek supply, 4 mi. through wood-stave pipe, gravity flow; re-use, 40%; net CONSUMPTION, 2.0 tons per ton milled.

Building: Steel and Gunite; cement floors sloping 1/4 in. per ft. in wet part. Steam heat in severe weather. Sloping mill site.

Machinery handling: Power cranes throughout, supplemented by hand cranes in concentrator.

Power: Hydroelectric; purchased. Comes 75 mi. at 66,000 volts. Three @ 1,850-k.v.a. steam turbines at plant for stand-by; used about 20% of year when water is low. Motors, 550-volt, 60-cycle. CONSUMPTION, 29.52 hp-hr. per ton milled.

Transportation: C.P.R.R. at mill serves for both ore and concentrate. Ore comes 2 3/4 mi. in 70-ton gondolas; concentrate shipped 200 mi. to smelter at Trail.

Tailing: Impounded in connected tailing dams; water runoff regulated by spillways.

Summary. Four-stage crushing from 36-in. run-of-mine to <1/4-in. Grinding to 85% <200-m. in three stages, the first open-circuit, with a plethora of classifiers demanded by the fine grinding and large circulating loads carried. All-flotation differential concentration with rougher-scavenger routings on both lead and zinc streams and 2-step clean-

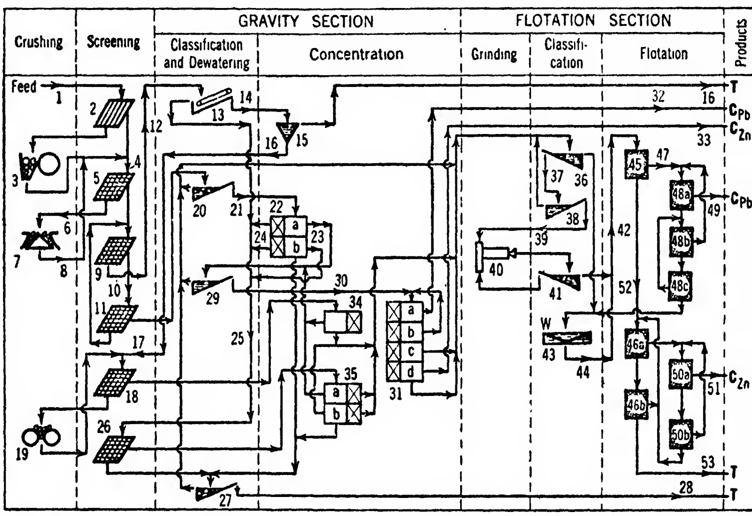
FIG. 116. CONSOLIDATED M. & S. Co., Sullivan mill.

ing of both rough concentrates. Lead middling is returned the second stage of the primary grinding circuit; zinc middling is reground in a separate circuit, scalped, and the scalped concentrate returned to the head of the zinc-cleaner circuit.

The difficulties in treating a finely disseminated complex ore are reflected in the recoveries that must be accepted here in order to maintain concentrate grades that will stand the 200-mi. haul to the smelter.

Eagle-Picher Mining & Smelting Co., Central mill. Fig. 117 (*Q* by Elmer Isern, Sup't of Milling; *153 A 89*).

Location: Picher, Okla.
Ore: Sphalerite and galena in a gangue of chert and jasperoid.
Capacity: 12,000 tons per 24 hr.
Assays: Feed: 4.5% Zn, 0.75% Pb; concentrate, 60.9% Zn, 80.3% Pb; tailing, 0.84% Zn, 0.09% Pb.
Recovery: 81% Zn, 88% Pb.
Ratio of concentration: 17 : 1.
Water: Comes from deep wells and from settling ponds at mill; 5 tons per ton of ore milled in circuit; as much as possible reclaimed.
Power: Company-generated by Diesel engines; comes 1 1/2 mi. at 23,000 volts; motors up to 2,200-volt, 25-cycle; consumption, 9.1 hp-hr. per ton milled.
Labor: 85 tons per man-shift, operating; 65 tons per man-shift, repairs.
Running time: 93%.
Mill building: Flat site. Steel and concrete, galvanized-iron enclosure; level concrete floors; heated; power cranes throughout.
Transportation: Mines 0.5 to 40 mi. distant, feed comes in by truck and by train; lead concentrate shipped 25 mi.; zinc concentrate, 200 mi. Moisture in jig concentrate, 2%; in flotation concentrate, 10%.



Legend for Fig. 117:

1. By railroad and truck to 5 hoppers; pan feeder.
2. Roller grizzly.
3. Two Webb City jaw crushers.
4. Belt conveyor; Butchart sampler; belt conveyor; 1 @ 6,000-ton bin; 5 feeders; belt conveyor; surge bin with feeders.

46. 14-cell zinc rougher-flotation machines; *a* = cells 1 to 10, *b* = cells 11 to 14.
47. Pump.
48. 8-cell lead cleaner; *a* = cells 1, 2, *b* = cells 3 to 5, *c* = cells 6 to 8.
49. Diaphragm pump; filters; railroad cars.
50. 10-cell zinc cleaner; *a* = cells 1 to 5, *b* = cells 6 to 10.
51. Diaphragm pump; filters; belt conveyor; railroad cars.
52. Pump.
53. Pump.

Summary. Two-stage crushing to <1 1/2-in. Tailing roughed out at 1 1/2~3/16-in. by sink-float cones. Rough middling recrushed and cleaned in two stages on jigs. <3/16-in. primary feed deslimed, and roughed and cleaned on jigs. Primary fines and jig middling classified, sands ground in closed circuit, and combined primary and reground feed concentrated by differential flotation.

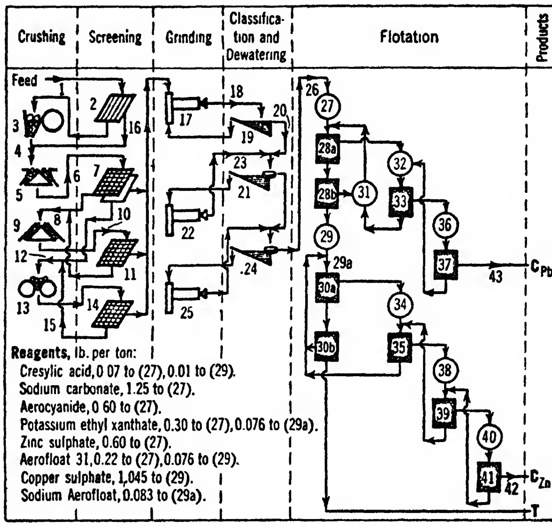
Mount Isa Mines, Ltd., Fig. 118 (*IC 7073; 116 Aa 482*).

Location: Mount Isa, Queensland, Australia.
Ore is an extraordinarily fine grained intergrowth of galena, sphalerite, pyrite, marcasite, pyrrhotite, chalcopyrite, sulphosalts of silver, and dolomite, in carbonaceous shales which contain both fixed carbon and more or less volatile hydrocarbons. Some of the pyrite (the oldest geologically) is apparently coated with carbonaceous material, since it floats despite high concentrations of cyanide and alkali, although it can be depressed by carbon depressants such as starch and protein-type colloids. Oxidation is very rapid, so that mining is planned to allow a minimum of time between breaking and milling.
Capacity: 1,840 tons per 24 hr.
Assays: See Table 88.
Recovery: See Table 88.

Table 88. Assays and recoveries at Mount Isa

Material	Weight, %	Assays			Recovery, %		
		Pb, %	Zn, %	Ag, oz. per ton	Pb	Zn	Ag
Feed.......	100.0	8.9	9.8	6.5	......	......	......
Lead conc..	19.1	39.1	10.4	27.2	83.5	......	79.8
Zinc conc...	9.3	1.7	52.7	2.4	......	49.9	......
Tailing.....	71.6	1.8	4.1	1.5	......	......	......

Ratio of concentration: Pb, 5.1 : 1; Zn, 11 : 1.
Water: From mine, supplemented as necessary by reservoir water brought 20 mi. Mine water contains over 3,000 parts per million of salts, principally Ca, Mg, Na, SO_4, and Cl ions; it is added to mill tailing so that some conditioning takes place through the tailing pond; if added directly to mill circuit, reagents, particularly Aerofloat, must be increased immediately; in any case, reagent consumption is high.
Power: Generated at plant by steam-turbine alternator at 3,300-volt, 3-phase, 50-cycle, using pulverized coal for steam making. Motors are 3,300-volt for 75-hp. upward; 440-volt below. Cost, distributed, 0.67¢ per kw-hr. (1938). CONSUMPTION, hp-hr. per ton: crushing, 2.80; grinding, 23.80; flotation, 12.30; concentrate handling, 1.00; tailing disposal and water return, 2.35; lighting, 0.60; total, 42.85.
Labor: Tons per man-shift, total, 30.5.
Running time: 98.6%.
Mill building: Slightly sloping site. Steel and concrete.
Machinery handling: Cranes in crushing, and grinding and classifier bays.
Tailing disposal: 1 @ 6-in. Wilfley pump raises tailing through a 12-in. wood-stave pipe to an elevated launder system, whence it flows to a tailing dam where it is discharged through spigots along the dam crest. The face is maintained at a 1-to-1 slope. The launder is lifted in 10-ft. steps and moved back 30 ft. at each lift. Reclaimed water is returned by pontoon pumps.
Distances: Mill at mine. Lead smelter at mine. Zinc is shipped 600 mi. by rail to Townsville, thence by steamer to Tacoma, Wash.
Costs: Crushing, $0.116; grinding, 0.227; classification, 0.015; flotation, 0.324; concentrate handling, 0.010; tailing disposal, 0.043; superintendence and miscellaneous, 0.177; total, $0.912 (1938).



Legend for Fig. 118:

1. Ore passed through 14 × 20-in. grizzlies underground. 1,600-ton (1,100 live) bin; 2 @ 36-in. apron feeders, 10-hp.

2. 2 variable-speed motors. Stationary-bar grizzlies, 2 1/4-in. spacing.

3. 2 @ 24 × 36-in. jaw crushers in parallel, 4-in. open setting, 224 r.p.m., 75-hp. motors (50 to 60 hp. consumed); manganese-steel plates, life of upper sections 20 mo., lower sections 12 mo.; toggles and seats, 16 weeks.

4. 1 @ 30-in. conveyor, 19 1/2° slope; 2 cone-feed conveyors in parallel with bipole high-intensity magnets.

5. 2 @ 5 1/2-ft. cone crushers in parallel, 485 r.p.m., 150-hp. motors (100 hp. consumed), set 3/8-in. Manganese-steel bowl and liner last 350 da.

6. Belt conveyor.

7. 1 @ 5 × 12-ft. 2-deck Niagara screen, 960 r.p.m., 7 1/2-hp. motor; 3/4 × 3/4-in. and 3/4 × 1/4-in. woven manganese-steel screens, life of upper screen 42 da., lower 60 da.

8. Belt conveyor.

9. 1 @ 4-ft. short-head cone crusher, 1/8-in. set, 485 r.p.m., 100-hp. motor (100-hp. consumed), 140 tons per hr. max. capacity. Bowl and mantle lives (Mn steel) 100 to 114 da.

10. Belt conveyor.

11. 1 @ 5 × 12-ft. Niagara screen, 1/4-in. aperture. Life of manganese-steel woven screen cloth, 18 da.

12. 2 conveyor belts in series, surge bin, belt feeder.

13. 1 @ 72 × 20-in. heavy-duty rolls driven 115 r.p.m. by 2 @ 125-hp. motors through V-belts.

14. 2 @ 5 × 12-ft. Niagara screens in parallel, 3/16-in. aperture.

15. Belt conveyor.

16. 1 @ 30-in. belt conveyor; shuttle conveyor; 6 @ 22 (diam.) × 45-ft. steel bins; 6 flat 36-in. feeder conveyors; 3 conveyors with weightometers.

17. 3 @ 8-ft. × 60-in. Hardinge ball mills, 20.8 r.p.m., 220-hp. motors (195 hp. consumed); 44,000 lb. forged chrome-steel balls, 4-in. renewals, 0.68 lb. per ton. Feed scoop, 42-in. rod.

18. 3 @ 14-in. pipe conveyors with 29-in. scoops, 38 r.p.m., 7 1/2-hp. motors.

19. 3 @ 8-ft. rake classifiers, 2 1/2-in. per ft. slope, 28 s.p.m., 15-hp. motors, overflow 70% solids with ball-mill feed at 90% <1/4-in.

20 4-in. pump.

21. 3 @ 20 (diam.) × 16 × 36-ft. bowl-rake classifiers, 2-in. per ft. slope, 3.3 r.p.m. and 17 s.p.m., 25-hp. motor (18 consumed). Overflow aver., 42% solids; 200 to 220 tons per hr. total feed into each mill (including circulating).

22. 3 @ 8-ft × 60-in. Hardinge mills in parallel; 20.8 r.p.m., 220-hp. motors (205-hp. consumed); 41,500 lb. of 2-in. alloy-cast-iron balls, 0.84 lb. per ton. Feed scoop, 54-in.

23. 2 @ 14-in. pipe conveyors in series, each mill; 31 r.p.m., 36-in. scoops.

24. 3 @ 18 (diam.) × 8-ft. bowl-rake classifiers, 2 r.p.m., 16 s.p.m. Overflow held at 33 to 38% solids to effect differential overgrind of sulphides, 76% <325-m.; contains 90% of the galena.

25. 1 @ 8-ft. × 60-in. Hardinge ball mill.

a An infrasizer test on this product showed:

Microns......	>56	40	28	20	14	10	<10
Weight, %....	30.0	8.8	10.0	7.2	5.6	5.2	33.2

Summary. Four-stage crushing from 14-in. to 1/4-in. 3-stage grinding to 85% <200-m. Differential flotation with two cleanings of lead concentrate for local smelting and three cleanings of zinc (with low recovery) for 10,000-mi. shipment. This ore requires extremely fine grinding for liberation and is so active chemically that with the long grinding time harmful surface sulphide reactions and slime coating occur to an extent that renders all flotation reluctant and selection highly difficult.

Anaconda Copper Co., Zinc plant (*Q* by T. M. Morris) crushes from run-of-mine to <1 1/2-mm. in five stages comprising two jaw-crusher stages, each with scalping screens, and 3 closed-circuit roll stages. Grinding to 65 *mog* is one-stage closed-circuit. Flotation (Fig. 119) is rougher-scavenger bulk flotation on the primary stream; 3-step cleaning of

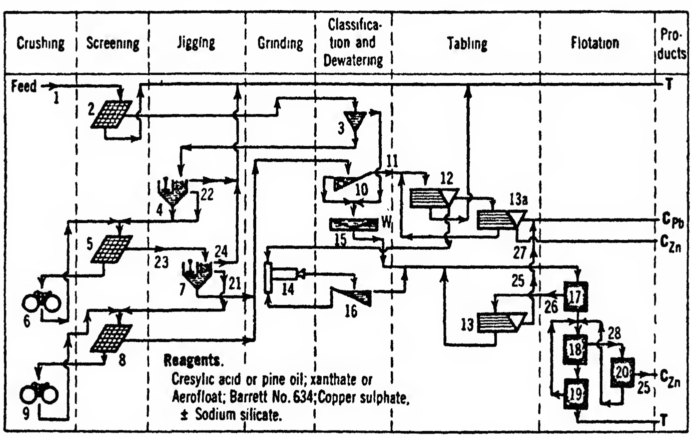
Fig. 119. Anaconda Copper Co., zinc-plant flotation.

This flowsheet constitutes a distinct departure from flowsheets previously described for zinc-lead separation.

Tri-State tailing retreatment. Fig. 120 (*138 #12 J 38*).

Ore: Tailing piles from old gravity mills; sphalerite with more or less galena in chert and limestone.
Capacity: 40 to 125 t.p.h. is the usual range.
Assays: Feed, 2 to 4% Zn; concentrate, 60% Pb, 60 to 62% Zn; tailing variable according to economics of operation.
Costs: Range is 20 to 45¢ per ton of feed, average about 30¢. Transport to mill, 4 to 10¢ per ton.



Legend for Fig. 120:

1. By truck from tailing piles. 21.4 cu. ft. per ton of loose tailing.
2. Scalping screen; baffled wash trommel or shaking screen.
3. Deslimer of rake, drag, or automatic-cone type; mechanical preferred on account of smaller headroom loss and more regular sand-discharge rate; <65-m. overflow.
4. 1 @ 42×48-in. 6-cell Cooley-type roughing jig; 6- to 8-in. beds carried; 90 to 120 @ 1- to 2-in. s.p.m.; 25 to 30 tons per hr. capacity. Usually run with split feeds, i.e., as 2 to 6 jigs in parallel.
5. Screen, 1/8 to 1/4-in. aperture; trommel or vibrating.
6. Rolls.
7. Chat-roughing jig.

22. 50 to 70% of jig feed.
23. 25 to 50% of original mill feed.
24. 50 to 60% of jig feed.
25. 60 to 70% of total concentrate; 60 to 62% Zn.
26. 35 to 40% Pb.
27. 60% Pb.
28. About 57% Zn.

Summary. Waste scalped out on jigs; jig middling crushed in rolls, sands treated on tables to yield concentrate and tailing; middling reground and floated with original slime.

Treadwell Yukon Corp., Ltd., Elsa mill (*Q*), at Mayo, Yukon Territory, treats 168 tons per 24 hr. of lead-zinc-iron sulphide ore in a quartzite-schist-carbonate gangue by one-stage crushing in 2 @ 4-in. reduction gyratories, one-stage closed-circuit grinding to 8% >48-m., and simple bulk flotation as shown in Fig. 121, using American Cyanamid R-242, amyl xanthate and cresylic acid, all fed to the ball mill. Feed assays 55 oz. Ag and 4% Pb; concentrate, 430 oz. Ag, 26% Pb, 20% Zn, 15% Fe, and 7% insol.; tailing, 8 oz. Ag, 1% Pb, and 0.5% Zn. Recovery averages 80% Ag and 70% Pb with a 10 : 1 ratio of concentration. Concentrate is shipped 1,800 mi.

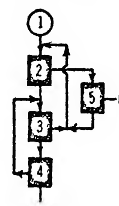

Fig. 121. Treadwell Yukon Corp., Elsa mill flotation.

This is an example of extremely simple treatment of a complex ore in which silver is the predominant value. Tonnage is small, ratio of concentration fairly high, and despite the long haul to the smelter and a probable zinc penalty, differential flotation with the necessary finer grinding is not attempted.

Eagle-Picher Lead Co., Montana Mines. Fig. 122 (*Q* by E. H. Crabtree, Jr., Mill Sup't; *IC 6497*).

Location: Ruby, Ariz.

Ore, approximate composition: Galena, 3.6%; marmatite, 4.6%; pyrite, 4.2%; small amounts of chalcopyrite and tetrahedrite. The pyrite carries gold; the tetrahedrite, associated with the galena, carries silver. Gangue is quartz and diorite with, occasionally, considerable clayey material.

Capacity: 415 tons per 24 hr.

Assays: See Table 91.

Recovery: See Table 91.

Table 91. Composite assays and recoveries at Montana Mines for the year 1937

Material	Assays					Recoveries, per cent.				
	Percentages			Oz. per ton		Pb	Zn	Fe	Au	Ag
	Pb	Zn	Fe	Au	Ag					
Feed	3.1	3.1	1.9	0.054	5.18	100	100	100	100	100
Lead-iron conc.	42.2	7.6	16.6	0.653	63.14	93.5	15.6	54.0	82.3	82.7
Zinc conc.	3.6	55.4	3.0	0.094	10.73	4.5	71.6	5.9	6.9	8.3
Tailing	0.07	0.44	0.86	0.0065	0.519	2.0	12.8	40.1	10.8	9.0

Ratio of concentration: 6 : 1 (total concentrate).

Labor: American and Mexican. Tons per man-shift: operating, 23.1; repairs, 130.1.

Running time: 94%. Principal cause of delay, repairs to flotation machines.

Water: Storage from local rainfall is normally sufficient. A stand-by pumping station is located on the Santa Cruz river, 15 mi. away, delivering through a 4-in. heavy duty lap-welded pipe line against a total head of 2,075 ft. (1,490 ft. static, 585 ft. friction). Cost (1930) about 25¢ per 1,000 gal. Gross consumption, 4 tons per ton milled; 95% re-used.

Building: Wood with corrugated iron sheathing; concrete floors, unheated; sloping site.

Machinery handling: Hand crawls in crushing plant; chain blocks in concentrator.

Power: Diesel power plant at mill; motors, 220-volt, 60-cycle; consumption, 22 hp-hr. per ton milled.

Transportation: Nearest railroad, 40 mi. Mill at mine; trailer trucks (12-ton capacity for lead concentrate; 11-ton for zinc) make a round trip to railroad in about 16 hr. at a cost (1930) of about 11¢ per ton-mile. Lead concentrate is shipped to El Paso; zinc to Amarillo, Tex.

Tailing: Pumped 800 ft. through heavy-duty flanged pipe to a dam. Clear water overflow (75% of tailing water) pumped back to storage reservoir.

Costs (1930): \$1.36 per ton operating, of which crushing comprised 23.7%, grinding 18.5%, and flotation 44%. Flotation reagent cost was 32¢ per ton.

FIG. 122. EAGLE-PICHER LEAD CO., Montana Mines.

Summary. Crushing from run-of-mine (head-size) to ball-mill feed in two stages comprising jaw crusher and rolls, both in open circuit. Grinding to 27% >65-m., 45% <200-m. flotation feed in one stage, closed-circuit. All-flotation differential concentration, making bulk concentrate by a 3-stage rougher-scavenger flow on the primary run with middling regrind, cleaning once, dewatering to remove soluble copper, and then separating lead from zinc, using sodium sulphite and zinc sulphate, operating on a rougher-scavenger flow with middling regrind.

Gold, associated with the pyrite, is an important element in this ore, which explains the making of bulk concentrate on which a high concentration of sodium sulphite can be used to depress sphalerite without affecting pyrite.

Shenandoah-Dives Mining Co. Fig. 123 (*Q* by A. J. Yahn, Mill Sup't, and D. M. Kentro, Ass't Mill Sup't).

Location: Silverton, Colo.
Ore: Galena, chalcopyrite, sphalerite, and pyrite with Au and Ag in quartz.
Capacity: 700 to 780 tons per 24 hr.
Assays: See Table 92.
Recoveries: See Table 92.

Table 92. Assays and recoveries at Shenandoah-Dives

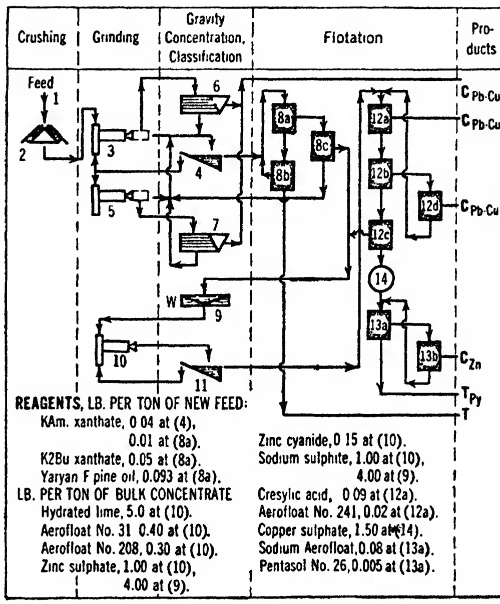

FIG. 123. SHENANDOAH-DIVES MINING CO.

Summary. Two-stage crushing (one at mine); one-stage closed-circuit primary grinding and one-stage closed-circuit regrind of bulk concentrate. All-flotation concentration comprising a bulk float by rougher-scavenger flow, followed by depression of zinc and iron and reflotation of zinc.

Here (in contradistinction to Fig. 122) the gold is associated with chalcopyrite, so that after making a bulk float, zinc and iron are depressed by lime, zinc sulphate, cyanide, and sodium sulphite, and the zinc thereafter reactivated preferentially by copper sulphate.

United States Smelting, Refining & Mining Co., Midvale plant. Fig. 124 (*Q* by R. A. Pallanch, Mill Sup't; *IC 6492*).

Location: Midvale, Utah.
Ore: Comes from two company mines and from a variety of custom sources. Principal sulphide minerals are galena, sphalerite, marmatite, and pyrite with minor amounts of chalcopyrite. Gangue is principally quartzite with some lime carbonates and considerable clayey material. A typical mill feed would approximate galena, 10%; sphalerite (or marmatite), 12%; pyrite, 20%; chalcopyrite, 1%; with Au, 0.05 oz. per ton, and Ag, 3 to 5 oz. per ton. Pyrite and galena are fairly coarse grained but sphalerite is more finely disseminated, requiring a grind to 5% >65-m. to free it satisfactorily. Galena sometimes somewhat sulphatized; lead content of both lead-circuit and final tailings increases with increase in this condition. Ore contains 5 to 7% moisture. The higher percentage causes trouble throughout the crushing, conveying, and feeding.
Capacity: 1,700 tons per 24 hr. max.
Labor: American. Tons per man-shift: operating, 25; repairs, 200.

Running time: 99%. Principal loss due to repairs.

Water: Comes by canal 16 mi. from Utah Lake. 100-ft. lift at plant consumes 45 hp. No reclamation. CONSUMPTION: 4 tons per ton of ore.

Building: Steel frame, Gunite walls, concrete floors. Heated. Level site.

Machinery handling: Power cranes in crushing and grinding plants; chain blocks in concentrator.

Power: Purchased. Comes 135 mi. at 44,000 volts. Motors, 440-volt, 60-cycle. CONSUMPTION: 33 hp-hr. per ton of ore, distributed as follows: crushing and conveying, 5.6%; grinding, 33.8; flotation, 30.4; tabling, 0.9; dewatering, 4.0; pumping, 22.7; water supply, 3.7%.

Transportation: D. & R. G. R.R. at plant. Ore comes 16 mi. in standard-gage 50-ton gondolas. Lead concentrate shipped 1/4 mi.; zinc, 500 mi.; pyrite, 20 mi.

Tailing: Impounded in ponds; clear overflow to Jordan River.

Legend for Fig. 124:

1. Crushing-plant (notes 1 to 14) capacity, 1,000 tons per 8 hr. Feed arrives in gondola cars (8 spotted at a time), is discharged into 2 @ 75-ton track hoppers with arc gates, thence by 2 @ 36-in. pan feeders arranged to permit mixing of two ores, and 1 @ 30×15 1/2-in. chain-bucket elevator (80° slope, 30-ft. lift, 50 f.p.m.) to

38. 1 @ 2-in. Wilfley pump.

39. One of 7 units, providing for separate dewatering of 7 grades of concentrate. The flow and apparatus in each unit are as follows, except as indicated: 1 @ 50×10-ft. thickener. (The overflow, in the unit treating concentrate from (28*a*) goes to a second 50×10-ft. thickener, which makes clear overflow and a spigot product that returns to cell 6 of item (27).); 1 @ 6-ft. American filter (5 @ 10-leaf filters are available; 2 are used for lead, 1 for zinc, and 2 for iron); lead cake, 8 to 10% water; zinc, 9 to 11%; iron, 10 to 12%; 5 @ 100-ton cake bins; cars to smelter.

40. Added at (21) in Unit 4 only.

41. Not added at (22) in Unit 4.

42. To cell 1 of (25).

43. To cell 4 of (25).

44. To cell 5 of (25).

45. To cell 2 of (27).

46. In unit 4 only.

Summary. Crushing from large head-size to <3/4-in. rod-mill feed in 3 stages, comprising gyratory, open-circuit rolls, and closed-circuit rolls. Grinding to 8% >65-m. flotation feed in a two-stage rod- and ball-mill series with the rod-mill circuit only partially closed. Concentration by preferential flotation of lead, zinc, and iron in order, adding sodium sulphite, zinc sulphate, and powdered gypsum in the initial conditioning; copper sulphate to re-activate zinc and sodium bichromate to depress lead in the zinc circuit; and sodium sulphide as an iron activator. Lead-flotation pulp follows a simple rougher-scavenger routing; zinc flotation is by the same flow, but two middlings are made and the lower-grade is reground before recirculation. The pyrite circuit is once-through, making two grades of concentrate. Flotation tailing is scavenged on tables.

This flowsheet takes advantage of the relatively coarse aggregation of galena and pyrite by confining regrinding to locked-sphalerite middling; and it guards against unsuspected losses in unfamiliar complex custom ores by use of scavenger tables. It is unique as of today in the failure to clean rougher concentrate except in so far as this is effected by counterflow of middling. Cleaning of zinc concentrate would normally be expected in view of the distance the concentrate is shipped. Power consumption is high but not excessive when the low over-all ratio of concentration (about 2 : 1), the complexity of the ore, requiring three flotation steps, and the extensive pumping following from this fact and the level site are considered.

San Francisco Mines of Mexico, Ltd. Figs. 125 and 126 (*Q* by H. B. Hanson, Gen'l Sup't, and G. O. Deshler, Mill Sup't).

Location: San Francisco del Oro, Chihuahua, Mex.

Ore is generally a lead-zinc-iron-copper complex carrying gold and silver, but comes from a number of veins, each with a different type of mineralization and each oxidized to a different extent. Each ore responds best to a specific treatment, but in order to avoid too great complexity in milling, the various ores are combined, through large (10,000-ton) crushed-ore storage pockets, into two classes, *viz.:* one comprising unaltered and slightly (10% or less) oxidized sulphides, and one consisting of mixed sulphide and highly (40% or more) oxidized minerals. The approximate composition of sulphide-mill feed in 1939 was: galena, 8%; sphalerite, 10%; chalcopyrite, 3%; pyrite, 5%; smaller amounts of chalcocite, arsenopyrite, and cerussite; fluorite, 17%; calcite, 10%; and insoluble 43%.

Gold occurs principally in arsenopyrite and silver sulphide; silver in galena, the copper sulphides, cerussite, and as an unidentified silver sulphide.

Oxide ore contains, in addition to the above sulphides, the carbonates of lead, zinc, and copper, anglesite, native copper, and minor amounts of pyromorphite, mimetite, vanadinite, wulfenite, and jarosite.

FIG. 125. SAN FRANCISCO MINES OF MEXICO, sulphide section.

Capacity: Sulphide ore, 1,600 tons per 24 hr.; carbonate ore, 330 tons.
Assays, recoveries, ratios of concentration: See Tables 93 and 94.
Water comes 1 1/2 mi. from the mine; it is pumped through a 10-in. line at an expenditure of 200 hp., 4 tons per ton of ore in circulation, 60% reclaimed. Storage at plant: 450,000 gal. fresh, 1,600,000 gal. return.
Power: Purchased; comes 68 mi. at 110,000 and 13,000 volts; motors 440-volt, 60-cycle. CONSUMPTION, 31.2 hp-hr. per ton milled.
Labor: Native. Tons per man-shift: operating, 12; repairs, 53.
Running time: 95%; loss due to repairs and power failures.
Building: Sloping site. Wood-frame, masonry and sheet-iron enclosure; cement floors, slope 1/4 in. per ft. Unheated.
Machinery handling: Hand cranes in coarse crushing and concentration sections; power crane in grinding section.
Tailing elevated by Wilfley pumps, then run about 1/3 mi. to storage dams by launders; sand spigots discharge around periphery, slime goes to center.
Transportation: Mines to mills, 1 1/2 to 2 mi. by aerial tram. Railroad spur at property. Lead concentrate shipped 210 mi. @ 8% moisture; zinc concentrate shipped out of country (normally to Europe), 9% moisture.
Cost: Sulphide and oxide milling (1935), $0.85 per short ton.

Legend for Fig. 126:

14. 1 @ 18-in. 20-cell M-S subaeration machine; (*a*) = cells 1 to 9, (*b*) = cells 10 to 20. Feed 7% >35-m., 42% <200-m. Sulphide concentrate taken from cells 1 to 4.
15. At cell No. 5.

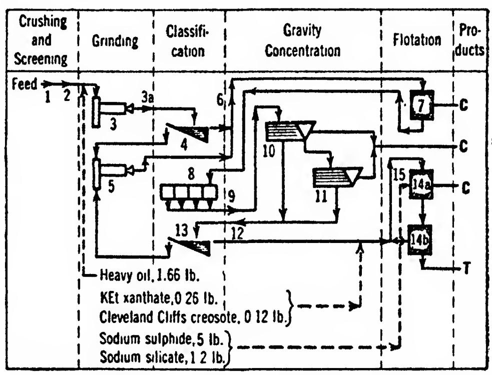

FIG. 126. SAN FRANCISCO MINES OF MEXICO, oxide section.

Summary. SULPHIDE MILL: 3-stage crushing to <1/2-in.; 2-stage grinding with gravity concentrate scalped out on tables between stages. Differential flotation with 3-stage roughing-scavenging in both lead and zinc sections; rough concentrates cleaned twice in both lead and zinc sections and middlings in both sections tabled for lead, before recirculation.
OXIDE MILL: 3-stage crushing to 1/2-in.; 2-stage grinding with flotation and tables in the grinding circuit. Flotation of grinding-plant product by 2-stage rougher-scavenger routing.

The precious metals are the important elements in the lead concentrate, both sulphide and oxide, and grade is sacrificed to recovery. Zinc concentrate, with a long trip to the smelter, is run to a high grade with marked sacrifice of recovery.

International Smelting Co., at Tooele, Utah, has treated mixed oxide-sulphide Pb-Cu-Ag ores intermittently over the period since Feb. 1929 (*IC 6759*). The mill has a rated capacity of 300 tons per day. Feed to the plant is sampling-mill product from a cone crusher set

Table 95. Assays and recoveries at oxide-flotation plant, International Smelting Co.

Material	Assays						Recovery, per cent.			
	Per cent.				Oz. per ton		Cu	Pb	Au	Ag
	Cu	Pb	Fe	Ins.	Au	Ag				
Feed	0.18	18.43	7.32	56.4	0.0567	24.85	.....	.....	.....	.....
Conc	0.36	47.02	13.94	16.7	0.114	58.76	72.2	94.6	74.6	87.7
Tailing	0.08	1.58	6.56	79.69	0.023	4.87	.....	.....	.....	.....

at $^3/_8$-in. This is ground to 1 to 2% >65-m. in one stage in a ball mill in closed circuit with a rake classifier and then floated in 4 parallel rows of 18-in. M-S subaeration machines staged as in Fig. 127. Feed enters cell 2, with ethyl and amyl xanthates, Pentasol (frother), and sodium silicate; sulphide concentrate is roughed off and cleaned as shown. The remaining cells are for oxide flotation; reagents are sodium sulphide and sodium silicate for conditioning, the xanthates for collection and Pentasol. Step addition of reagents is necessary. Reagent consumption is: sodium sulphide, 6 lb. per ton; sodium silicate, 4 lb.; sodium amyl xanthate, 1.5 lb.; ethyl xanthate, 1.2 lb.; Pentasol, 0.30 lb. Variations in feed conditions are compensated for by change in the quantity and places of addition of the sodium sulphide. Assays and recoveries for Sept. 1930 were as given in Table 95.

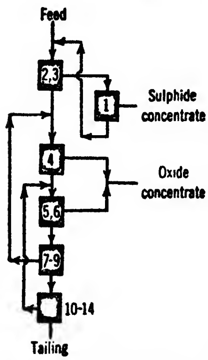

FIG. 127. INTERNATIONAL SMELTING CO., oxide flotation.

A 160-day mill test (*14 MMt 291*) crushing to $^3/_8$-in., jigging at $^3/_8$- to $^3/_{16}$-in., and $^3/_{16}$-in. to 14-m.; tabling coarse, medium, and fine sand products from hydraulic classification separately, and floating slime indicated recovery of 88 to 90% of the Cu, 95 to 98% of the Pb; 60 to 65% Fe; 80 to 85% Au; 88 to 93% Ag in the gravity-plant feed and 80% of the slime lead by flotation in a combined concentrate carrying 45 to 55% Pb; corresponding rejection of insoluble was 70 to 83% in the gravity treatment and 80 to 85% in the flotation tailing.

International Smelting & Refining Co., Ophir Hill tailing plant. Fig. 128 (*A TP 1239; 141 #5 J 52*).

Location: Ophir, Utah.

Ore: Old gravity sulphide tailing assaying Cu, 0.65%; Pb, 2.2%; Zn, 2.1%; Fe, 3.1%; insol., 58.6%; CaO, 2.0%; Au, 0.005 oz.; Ag, 2.6 oz. per ton. Size varies from coarse sand to slime of semicolloidal nature. Variation is relatively extreme both vertically and horizontally throughout the dump. Oxidation likewise ranges from 25 to 75% of Pb oxidized. Dump tonnage, 390,000.

Capacity: 720 tons per 24 hr. maximum.

Power: Purchased. Comes 20 mi. at 44,000 volts. 440-volt motors. 110-volt lighting. CONSUMPTION, hp-hr. per ton: scrubbing and agitating, 3.8; conveying and elevating, 0.4; grinding, 11.0; flotation, 3.8; pumping pulps, 1.1; filtration, 1.3; lighting and miscellaneous, 0.8; total, 22.2.

Labor: 15.5 tons per man-shift, total personnel.

Water: Comes 1 mi. by gravity to a 120,000-gal. storage tank giving 150-lb. pressure on line at mill.

Assays: See Table 96.

Recovery: Pb, 90.7%; Cu, 89.9%; Ag, 88%.

6. 2 @ 20×15-ft. downcast Devereaux agitators, 60-in. ship-type impeller 5 ft. above bottom in 6.5 (diam.) × 10-ft. well, 88 r.p.m., 25-hp. motors, V-belts. Rubber-lined valves and rubber-bushed spigots on discharge line.

7. 1 @ 14-in.×52-ft. bucket elevator, 396 f.p.m., 7.5-hp. motor.

8. Washings from dumped rock.

9. Tonnage sampler.

10. 2 @ 6×8.5-ft. modified Marcy ball mills, 23.5 r.p.m., 150-hp. motors, chain drive. Grates plugged with wood wedges to within 4 slots of axis. 50 to 65% solids, according to size of feed. Charge, 14,000 lb. cast-steel balls; renewals 2-in.; CONSUMPTION, 1 lb. per ton feed; liner, 0.09 lb. per ton. Pulp temp. maintained 80° F. in summer and 90° in winter. Feed: 32% >35-m., 39% <200-m.

11. 2 @ 6×20-ft. duplex rake classifiers, slope 2 1/4 in. per ft., 16 s.p.m., 10-hp. motors, V-belts. Overflow, 22% solids.

12. 2 @ 8×5-ft. surge tanks agitated by circulation through 3-in. Wilfley pumps. Siphon discharge.

13. 2 @ 7-cell 56-in. square Fagergren cells in parallel. Direct drive, 585 r.p.m., 7.5-hp. motors. Temp., 58° F. Feed: 1.7 >65-m., 69% <200-m.; 2.2% Pb. Tailing: 0.4% Pb.

14. 2 @ 1-cell 56-in. sq. Fagergren cleaner cells in parallel. 600 r.p.m., 7.5-hp. motors.

15. 2 @ 3-in. Wilfley pumps, 1,160 r.p.m., 10-hp. motors.

16. Geco automatic sampler.

17. 2 @ 4-in. Wilfley tailing pumps, 875 r.p.m., 15-hp. motors. Lift 25 ft. to 12,000 ft. 12×12-in. tailing launder, fall 1/4 in. per ft., and 1,800 ft. of 12×12-in. V-type distributing launder behind sand banks on tailing pile.

18. 2 @ 2-in. Wilfley pumps, 1,160 r.p.m., 10-hp. 25-ft. lift.

19. 1 @ 30×10 ft. thickener, 1 rev. in 4.75 min., 2-hp. motor. Temp. 60° F.

20. 1 @ 12-in.×30-ft. bucket elevator, 283 f.p.m.

21. 1 @ 8×8-ft. Oliver filter, 0.21 r.p.m., 5-hp. motor. Feed 100 to 120° F. Cake 11 to 18% water according to character of mill feed. Filter cloth water washed about 3 hr. each day to prevent clogging by $CaSO_4$.

22. 100-ton bin. 20- and 30-ton semi-trailer Diesel dump trucks to smelter, 25 mi.

Summary. Disintegration in a rotary washer, one-stage closed-circuit grinding, rougher-cleaner flotation with return of cleaner tailing to the grinding circuit. No attempt at differential separation of sulphides.

Buchans Mining Co., Ltd. Fig. 129 (*112 A 841*).

Location: Buchans, Newfoundland.

Ore: A highly complex heavy sulphide in a barite gangue; average assay: 0.05 oz. Au and 3.5 oz. Ag per ton, 1.5% Cu, 8% Pb, 17% Zn, 8% Fe, 30% $BaSO_4$, about 10% combined quartz and calcite, and small amounts of sericitic schist. Dissemination ranges from dense fine-grained ores with comparatively high contents of chalcopyrite and pyrite and little galena to coarse-grained ore of relatively low iron and copper content. Considerable surface oxidation of the sulphide minerals exists.

Capacity: 1,200 t.p.d.

Assays: See Table 97.

Recovery: See Table 97.

Table 97. Assays and recoveries at Buchans mill (1933)

FIG. 129. BUCHANS MINING CO.

Labor: Operating, men per shift: crushing, 3; grinding, 1; flotation, 2 1/3; pumping, 1; concentrate handling, 2 2/3; clean-up, 1; supervision, 1; total, 12, or 33.3 tons per man-shift; repairs and maintenance, 1, or 400 tons per man-shift.

Mill building: Site substantially level. Steel-frame, concrete floors, corrugated transite covering. Steam heat at 1 to 10-lb. pressure to radiators and unit heaters; 37,500 sq. ft. of radiating surface required to heat 3,020,000 cu. ft. of building (203,400 sq. ft. of roof and side walls) during the cold months (30° F. aver. temp.; 6 to 16° aver. minimum). Average annual cost of heating, 3 1/2¢ per ton milled; cold-weather cost, 9¢ per ton.

Costs (1933), ¢ per ton milled: Crushing and conveying, 40; grinding and classifying, 7.3; flotation, 58.4 (reagents 48.9¢ of this); concentrate handling, 9.8; power, 11.9; heat, water and light, 5.2; miscellaneous supplies, 1 0; testing, sampling, and assaying, 3.8; supervision, 2.0; total, $1.03.

Summary. Two-stage crushing to 1-in. ball-mill feed. One-stage grind in ball mills to 100 *mog*. Lead-copper flotation by roughing and 2-step cleaning with cleaner tailing scavenged for lead on tables and reground before recirculation. Lead depressed from lead-copper bulk concentrate. Zinc floated by rougher-scavenger routing with 2-step cleaning of concentrate. Zinc middling reground and refloated in a separate circuit, and a lead-iron concentrate skimmed out of the float before return to the zinc-cleaner circuit.

This flowsheet is an interesting modification of standard procedure for complex ores to adapt to unusual ore and smelter conditions. Galena is sluggish owing to surface oxidation and will neither float to a satisfactory extent originally nor will that floated under intense roughing conditions refloat wholly under the mild treatment in the cleaners that is necessary to make a lead concentrate of required grade; hence tables must be used to aid lead recovery. Iron, on the other hand, is not sufficiently depressed under the intense flotation conditions required to bring up all of the floatable lead in the zinc circuit, and is, therefore, removed from the intensely floated zinc-scavenger froth by tabling, the practice being rendered economic by the presence of sufficient gold, silver, and lead that separate with it to render the concentrate salable.

Callahan Zinc-Lead Co., Duquesne mill. Fig. 130 (*A TP 1410*).

Location: Near Nogales, Ariz.

Ore: Galena, chalcopyrite, sphalerite, pyrite with limestone, quartz and garnet; relatively coarse dissemination, sulphides largely liberated at 65 *mog*.

Capacity: 120 t.p.d.

Assays: See Table 98.

Recoveries: See Table 98.

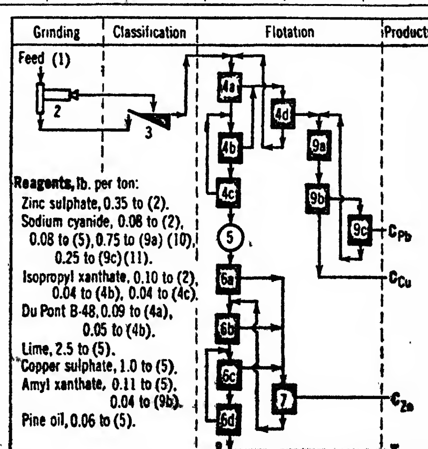

FIG. 130. CALLAHAN ZINC-LEAD Co., Duquesne mill.

Summary. Rougher-scavenger routings for making Pb-Cu bulk and zinc concentrates from the primary stream, with one cleaning of each. Clean bulk concentrate separated by depressing chalcopyrite with a high concentration of cyanide ion (Sec. 12, Arts. 10 and 47).

30. MAGNESIUM

Uses. Magnesium is used in metallic form in explosives, starshells and flares, and for high-intensity lighting in photography; as an ingredient of Thermit; as a catalyst; as a dehydrator for oils; and as a deoxidizer and scavenger in purification of nonferrous metals. Its primary use, however, is in light-weight high-magnesium (90 to 95%) alloys for automobile and aircraft construction. Such alloys have a higher tensile strength pound-for-pound than steel. They are also used for making large and intricate castings, which are much stiffer than the corresponding alloys of aluminum and have the same tensile strength.

Ores. The economic minerals are the anhydrous sodium-magnesium chloride obtained from brines, carnallite, magnesite, and dolomite.

Production is increasing rapidly.

Prices have dropped more or less steadily as the technique of production has been perfected. Average price, per lb., 99.8% ingots: 1929, 56¢; 1932, 29¢; 1937, 30¢; 1939, 30¢; 1938, 27¢; 1942, 22.5¢.

Treatment. Concentration of magnesium minerals other than hand picking of magnesite with or without cobbing was not practiced pre-war, but flotation of magnesite from silicates is reported as a laboratory procedure (Sec. 12, Art. 52), and promising results have been obtained by sink-float (Sec. 11, Table 94). The usual commercial methods comprise electrolysis of relatively pure fused compounds, $MgCl_2$, the double chloride of Mg and Na or K, or of MgO dissolved in a fused bath of mixed Mg, Ba, and Na fluorides. Considerable war-time production was effected by distillation from magnesium oxide or from calcined dolomite at very low pressures; the comparative economy of the method is not yet established. Sea-water brines were also a war-time source of electrolytic-tank feeds.

31. MANGANESE

Uses. Manganese is not used commercially in the free state. Its greatest use is in the steel industry where it is introduced in the form of the iron alloys, FERRO-MANGANESE, containing about 80% Mn, and SPIEGELEISEN, containing 15 to 30% Mn. Probably the next most important use of manganese is as the dioxide (MnO_2), which acts as a depolarizer in dry batteries. This calls for a very high grade product containing about 80% MnO_2 and less than 1% iron. Other uses of manganese compounds are: oxidizing agent in the manufacture of chlorine, bromine, and disinfectants; drier in paints and varnishes; coloring agent in calico printing and dyeing; in making glass, pottery, brick, and paints. Manganese bronze is an alloy with copper which may or may not contain some iron; silver bronze, an alloy with aluminum, zinc, copper, and silver; manganese-titanium, an alloy of these metals with iron for use in the manufacture of special steels. See *IC 6768* and *IC 7145* for details.

a Figures mostly from *Mineral Resources*.
b Zinc residues from franklinite ore.

Ores. The usual economic minerals are pyrolusite, psilomelane, braunite, and wad. The manganese minerals as mined have specific gravities of 3.5 to 5, with average between 3.5 and 4; they are usually weakly magnetic. The minerals occur as nodules, lumps, pockets, stringers, or lenticular masses irregularly scattered through residual clays and weathered rocks. Domestic deposits are small. The common associates, beside the clay, are limonite, barite, ocher, bauxite, silica, and limestone. Manganiferous iron and manganiferous zinc ores are also important sources of the metal. Rhodochrosite occurs at Butte, Mont., in economic quantities.

Ores are graded as follows: (1) Battery ore, exceptionally high MnO_2 content; (2) ferromanganese stock, containing a minimum of 45% MnO_2 (aver., 48%), with Mn : Fe ratio of not less than 7 : 1 (usually 8 : 1), silica from 7 to 10%, and phosphorus 0.12 to 0.2%; (3) spiegeleisen stock, containing from 10 to 45% Mn and higher iron than in grade (2); (4) pig-iron stock, containing from 7 to 10% and upward of Mn.

The manganese in ferromanganese stock is paid for on a sliding scale depending on the manganese content; this practice is based on the fact that silica must be slagged off in making the ferromanganese and that the cost of such slagging-off is appreciable. Langhorne (*1928 Proc. Am. Manganese Prod. Assoc. 126*) states that it costs $10 more per ton of product to make ferromanganese from stock assaying 14.3% SiO_2 than from stock assaying 5.72% SiO_2; this amounts to 11¢ per unit of manganese on 42.3% Mn stock as against 48.6% Mn stock.

Production of the various classes of ore in the United States is given in Table 99. United States production by years is given in Table 100 and world production in Table 101. Analyses of various high-grade imported ores are given in Table 102.

g See Table 102.

Treatment. The method of concentrating depends upon the character of the ore deposit. When the ore is nodular, in easily disintegrated clay, and the nodules are of high grade, simple washing by log washer or wash trommel, supplemented usually by hand picking, is all that is ordinarily necessary.

Table 102. Analyses of imported high-grade manganese ores (*After Langhorne, 128 Proc. Am. Manganese Prod. Assoc. 126*)

Source	Assays, per cent.					
	Mn	Fe	SiO_2	Al_2O_3	P	Bases

a But see Fig. 138.

At EUREKA Co., Batesville, Ark., the ore is washed in a 30-ft. 2-log washer at 20 r.p.m. The log product is sent to a wash trommel (16-m.), then sized at 1/2-in. into coarse and fine shipping grades. The washed product contains about 42.5% Mn. The EMBREE IRON ORE Co. plant, Fig. 134, is more elaborate, including jigging of washer products.

When siliceous and other foreign matter occurs in the nodules, a more complicated plant involving crushing is necessary. The HY-GRADE mill, Fig. 136, is typical. When the ore occurs in hard rock, which must be mined with the manganese minerals, the flowsheet is commonly graded crushing followed by jigging and tabling. The PHILIPSBURG MINING Co. (Fig. 131) plant is an ingenious departure.

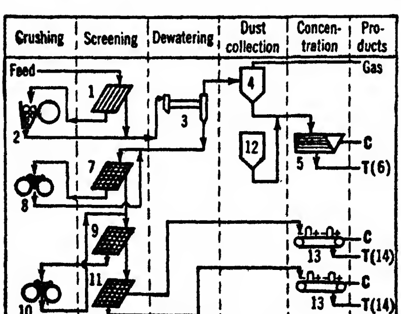
Wash ores, to be readily amenable to treatment, should carry better than 3% of manganese mineral. Leaner material can be handled, if it can be graded up by picking. In general the wash ores average about 10% Mn content. Some deposits run as high as 25 to 35% Mn. The character of the clay is important; if tenacious, capacity and grade of product will be much reduced and tailing loss high.

Manganese minerals have specific gravities high enough for separation from ordinary gangues by gravity concentration; they are also sufficiently permeable for high-intensity magnetic concentration, and are floatable with fatty-acid collectors. Sink-float separation has been tested (Sec. 11, Table 94); it should be useful on some of the washed material now picked and jigged.

Testing. Results of an extensive testing program on domestic ores are recorded in *IC 6768.*

Philipsburg Mining Co. Fig. 131 (*Q; IC 6768; 124 J 647*).

Location: Philipsburg, Mont.
Capacity: 75 to 100 t.p.d.
Ore: Nodules of soft pyrolusite and psilomelane in a gangue of quartz, kaolin, calcite, and iron oxides.
Assays: Feed, 30 to 35% MnO_2; concentrate, 70% MnO_2, <0.2% P, <6% Fe, ±10% SiO_2; tailing, 10 to 20% MnO_2.
Recovery is about 80% with no circulation of middling.



Legend for Fig. 131:

19. Pump.

FIG. 133. MANGANESE CORP. OF AMERICA.

Summary. Crude washed in a log-washer and bowl classifier to remove clay; hand picked for high-grade concentrate; crushed to <5/8-in. in one stage in closed circuit with a

log-washer; <$^5/_8$-in. material screened into five sizes down to 14-m. and the various sizes jigged separately; <14-m. classified extensively and the classified products tabled; jig middling recrushed and returned to primary circuit; table middling reground and returned to table circuit.

Embree Iron Ore Co. Fig. 134 (*IC 7145*).

Location: Embreeville, Tenn.

Ore: Psilomelane as nodules, softer lumps and light, porous particles; also some soft plumbagolike pyrolusite and wad; gangue is predominantly clay with some chert or quartzite grains. The nodules and lumps also contain very fine silica, limonite, and iron in an unidentified form.

Capacity: Washing plant, 18 tons per hr.; jig plant, 10 tons per hr.

Assays: Washing plant feed and log-washer tailing not sampled, but grab samples of latter range from about 2 to 11% Mn. Average washing-plant concentrate for 1939 assayed as shown in Table 103, item *Feed;* this is concentrating-plant feed. Ratio of concentration was 6 : 1. Jig-plant results are also shown in Table 103.

Table 103. Metallurgical results for jig plant, Embree Iron Ore Co.

Material	Dry long tons	Weight, per cent.	Assays, per cent.		
			Mn	SiO_2	Fe
Feed *a*	11,417	100.0	30.43	21.65	13.97
Jig-and-belt conc.	6,831	59.8	38.47	10.39	12.28

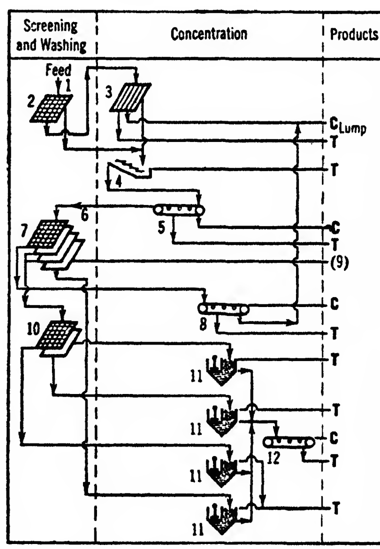
Jig and picked tailing *b*	2,641	23.2	10.24	46.78	22.26
Combined tailing	4,068	35.7	14.78	42.39	17.95

a Washing-plant concentrate.
b By difference. Calculation contains an assumption as to stockpile tonnage. Arithmetic average of jig tailing was 14.9% Mn.



Legend for Fig. 134:

1. Dump trucks; hillside hopper (*a*, Fig. 135) 48 ft. long with sloping bottom 45° at upper side and 30° toward front, plank on round timber.

2. Transverse horizontal stationary washing screen (Fig. 135). Aperture, 3 1/2-in. square, $^5/_8$-in. round rod. A nozzle stream sluices feed from hopper to screen and washes the oversize.

3. Horizontal steel-rail grizzly, 4×10-ft., 1-in. aperture. Lump oversize sledged to convenient size for handling. 3 men on this and (2).

4. 1 @ 25-ft. 2-log washer; slope, 2 in. per ft., 18 r.p.m.; feed entry about 2 ft. from overflow; spray on upper 8 ft.; 20-hp. motor drives washer and picking belt (5), 19-hp. average consumption.

5. Picking belt, 18 in.×28-ft., 30 f.p.m., 4 men picking rock and high-grade (70% MnO_2) concentrate.

6. By truck @ 1 mi. to storage bin similar to (1); belt conveyor.

7. Compound trommel: 36 in. × 10 ft., $^3/_4$-in. aperture cloth; 44 in. × 9 1/2 ft., $^1/_4$-in. aperture; 52 in. × 9 ft., $^1/_{16}$×$^1/_4$-in. and $^3/_{32}$×$^1/_4$-in. slotted cloth. Spray on outside screen. Slope, 1 1/4 in. per ft.; 10 r.p.m.

8. Picking belt, 18 in. wide, 30 f.p.m., 3 men picking waste and high-grade chemical ore.

9. Stockpile; can be concentrated almost to grade of present plant concentrate, but too fine for steel-plant use.

10. 3 1/2×8-ft. trommel, $^3/_{16}$- and $^7/_{16}$-in. round holes.

11. 4-cell McLanahan and Stone pulsion jig; each compartment, 48 in. long × 27 in., is independent and fed by a separate sized product as indicated.

12. Picking belt like (8); 1 man picking waste.

Fig. 134. Embree Iron Ore Co.

Transportation: Dump truck 0.65 mi. from mine to washing plant and 1 mi. thence to jig plant; concentrate, 12 mi. by truck to railroad; cost 50¢ per ton. Freight to Birmingham, Ala., is $1.80 per ton for less than 43% Mn and $2.90 per ton for higher grade.

Water: Washing plant, 500 to 600 g.p.m.; concentrating plant, 200 g.p.m.

Power: 213 hp. average total, including water supply; 71.1 kw-hr. or $0.88 per dry long ton of concentrate.

Labor: 8 men per shift at washing plant, 7 men and superintendent at jig plant.

Building: For general arrangement of plant see Fig. 135.

Cost of a plant to produce about 10,000 tons of concentrate per year was (1938) about $20,000 for a shovel, bulldozer, and dump trucks, and $40,000 for the washing-concentrating plant.

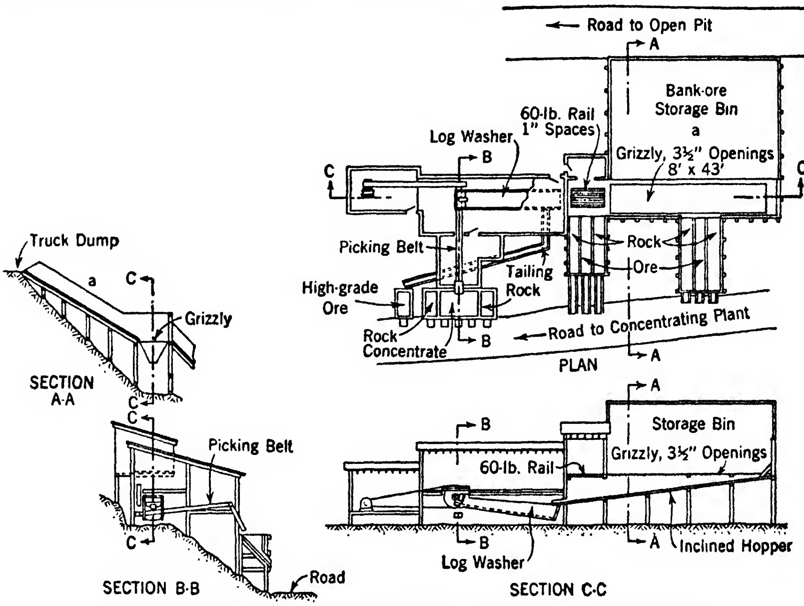


FIG. 135. General arrangement of washing plant, EMBREE IRON ORE CO.

Summary. Washing on a grizzly and in a log washer; washed lump concentrated by hand-picking and jigging.

Hy-grade Manganese Production and Sales Corp. Fig. 136 (*6768 IC 92*).

Location: Cedar Creek, near Woodstock, Va.

Ore: Pyrolusite and psilomelane with sandstone, chert, and quartz in limonitic clay.

Legend for Fig. 136:

1. Grizzly, 4 1/2-in. spaces.
2. Trommel, 1 1/4-in. holes.
3. Elmore washer.
4. Gyratory crusher.
5. Rolls, set 1/2-in.
6. Hum-mer screen, 1/2-in. aperture.
7. Hum-mer screen.
8. Drag classifier.
9, 10, 11. Hum-mer screens.
12, 13, 14. Harz-type jigs.
15. Hardinge ball mill.
16. Hydraulic classifier. Installation of this classifier lowered the tailing of tables (10) from 11% Mn to 2% Mn.
17. 3 shaking tables, each taking a separate spigot product.
18. 3 dewatering cones.
19. 2 slime tables.
20. James jig.
21. Middling.

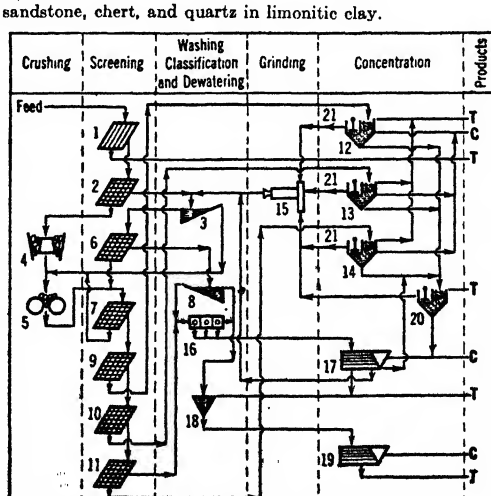

FIG. 136. HY-GRADE MANGANESE PRODUCTION & SALES CORP.

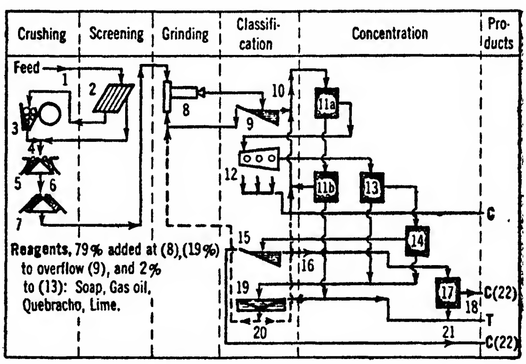
Summary. Two-stage crushing to <$^1/_2$-in.; all-gravity concentration by jigging of coarse sizes, and tabling of fine after classification.

Chocolate clays. The so-called chocolate clays of the BATESVILLE-CUSHMAN field in Ark. form a part of the matrix of the wash ores. The color is due to a manganese content of about 10% occurring as very finely disseminated oxide. It is normally discarded in washing. MILLER AND RINEHART (*125 J 899*) have operated a plant in which this material is disintegrated and washed in 30-ft logs, which discard overflow; log sand is screened at $^1/_8$-in. (it has already passed $^1/_4$-in.), oversize is crushed in rolls and recirculated, undersize is tabled. Table concentrate is sintered in a rotary kiln. Product assays about 28% Mn, 20% Fe, 12% SiO_2, 5% Al_2O_3, and 6% CaO; it is used as additional manganese in pig-iron furnaces.

Cuban-American Manganese Corp. Fig. 137 (*153 A 97*).

Location: Cristo, Oriente Province, Cuba.
Ore: Pyrolusite, psilomelane, manganite, and (rarely) wad in altered tuffs, with quartz, calcite, chlorites, sericites, iron oxides, clay, etc.; also greater or less amounts of soluble carbonates.
Capacity: 1,000 long tons (dry) per 24 hr.
Assays: Feed, 18% Mn; sinter, 51% Mn, 9% SiO_2.
Recovery: 86.8%.
Ratio of concentration: 3.3 : 1.
Water: From river, pumped $^1/_2$ mi., 150-hp. motors. CONSUMPTION, 8 tons per ton milled; 70% re-used.
Power: Purchased; comes 1 $^1/_2$ mi. at 2,300 volts. Motors, 440-volt, 60-cycle.
Labor: Cuban, 2.37 tons per man-shift, operating; 12 tons per man-shift on repairs.
Running time: 96%; loss due to power failures and general repairs.
Building: Sloping site. Steel frame, sheet-iron cover. Unheated. Floors in wet part slope $^1/_{16}$ in. per ft.; cement.
Machinery handling: Chain blocks throughout.
Transportation: Steam locomotive 1 mi. from mine to mill; concentrate (dry sinter) shipped 10 mi. to dock, thence to U. S.



Legend for Fig. 137:

1 By rail from mine; 120-ton track hopper; 1 @ 48-in.×11-ft. apron feeder.

2. 1 roll grizzly, 7 @ 48×1 $^1/_2$-in. rolls, 4-in. ring aperture.

3. 1 @ 36×48-in. jaw crusher, set for <4-in. ring; unreceivable oversize broken at crusher with pneumatic hammer.

4. 3 @ 1,000-ton cylindrical-steel bins, 24-in. apron feeders; belt conveyor with Merrick weightometer and automatic sampler.

5. 1 @ 4-ft. standard cone crusher, set $^3/_4$-in.

6. 1 @ 36-in.×50-ft. bucket elevator.

7. 1 @ 4-ft. short-head cone, set $^1/_4$-in. Water is added to the cone in variable amounts according to the quantity of clay in the feed.

8. 3 @ 6×12-ft. Marcy rod mills.

9. 3 @ 72-in. Akins classifiers with automatic density controllers.

10. Pump; distributor.

11. 3 @ 16-cell 24-in. M-S subaeration machines in parallel; *a* = cells 1 to 6, *b* = cells 7 to 16.

12. 3 Richards-Janney hydraulic classifiers to remove coarse concentrate, which floats with difficulty in cleaning and would otherwise build up in the cleaning circuit.

13. 3 @ 6-cell 24-in. M-S subaeration machines in parallel.

14. 1 @ 8-cell flotation machine.

15. 1 @ 6×100-ft. chain-drag classifier.

16. Pump.

17. 1 @ 9-cell flotation machine.

18. Thickened and fed to kiln.

19. 1 @ 40-ft. thickener.

20. Alternative according to character of ore.

21. 50-ton steel bins with screw feeders at bottom; full tanks are blown 5 to 10 min. with compressed air, allowed to settle, and slimes decanted. This treatment reduces moisture from 40% to from 18% to 23%. The method of concentrate dewatering, involving items 15, 17, 18, and 21, derives from the fact that the manganese minerals settle with extraordinary rapidity and cake badly when settled, so that thickeners, pumps, etc., handling concentrates clog badly and persistently.

22. Concentrates are mixed, in varying proportions to maintain moisture constant, in a 6×6×21-ft. chain mixing drag, then fed to 1 @ 9×213-ft. oil-fired rotary kiln where it is dried and sintered. A 72-in.×88-ft. Dwight-Lloyd sintering machine is a stand-by for the kiln; this, together with 1,850-ton concentrate storage, permits continuous operation despite kiln shutdowns for relining.

FIG. 137. CUBAN-AMERICAN MANGANESE CORP.

Summary. Three-stage crushing and one-stage closed-circuit rod milling to flotation-feed size. Soap flotation; rougher-scavenger flow with 3 cleanings of rough concentrate, coarse concentrate being classified out between rougher and cleaner and between recleaner and third cleaner.

Anaconda Copper Co., manganese plant. Fig. 138 (T. M. Morris, *PC; 129 J 207*).

Location: Anaconda, Mont.
Ore: Rhodochrosite with some sulphides in silicate gangue.
Capacity: 1,000 tons per 24 hr.
Assays: Feed, 20% Mn; concentrate, 39%, <6% SiO_2; tailing 5% Mn; nodules, 60% Mn, @ 7% SiO_2.
Recovery: 86%.
Cost: \$1 to 1.50 per ton of crude, estimated (*IC 6768*).

FIG. 138. ANACONDA COPPER CO., manganese plant.

Summary. Five-stage crushing to <1/4-in.; one-stage grinding to flotation-feed size. All-flotation concentration, in which sulphides are scalped out with sulphydric reagents in a simple rougher-scavenger-cleaner routing; whereupon rhodochrosite is soap-floated by one-stage roughing and scavenging and 2-stage cleaning.

Experimental. Since manganese in manganese concentrate is paid for on a sliding scale which increases with the manganese content, high concentrate grade is economically important apart from the factor of freight. Iron oxides are common contaminants. DeVaney and Coghill (*RI 2936*) report experiments comprising reducing roasting to convert the iron

oxides to magnetite, followed by low-intensity magnetic separation. Roasting alone increased the manganese assay of 3 southern concentrates about 10% of the unroasted assay (e.g., from 40% Mn to 44%), and magnetic separation produced a further lift to from 48 to 52% Mn content, the percentage increase being greater the lower the grade of the unroasted concentrate.

Tests. The U. S. Bureau of Mines tested a great variety of domestic ores by gravity concentration, magnetic separation with and without roasting, and by flotation. They report (*IC 6768; RI 3600, 3606, 3608, 3614, 3620, 3623, 3624, 3632, 3633*) on more than 100 ores and conclude that about 80% of them could be concentrated to an extent suitable for production of 80% ferromanganese, at the same time making second-grade products suitable for spiegeleisen or high-manganese pig iron. The usual method of treatment for oxide ores was washing to remove clay and other primary slimes, scrubbing if necessary, followed by jigging and/or tabling when the manganese minerals freed at suitable sizes. Fatty-acid flotation of the oxide manganese minerals, using sodium silicate as a dispersant, was usually effective. Sintering was usually practiced both because of the size requirements set by buyers and in order to raise concentrate grades. Attempts were made to improve the iron ratio by a reducing roast of concentrate followed by magnetic separation. Pyrite, when present, was removed by sulphydric collectors before flotation of manganese. The net result of the test work was to demonstrate that, under noncompetitive war-time conditions, many domestic manganese deposits can be made to yield low-grade ferromanganese stock, with low recovery, by relatively complicated and costly treatment.

32. MERCURY

Uses. The drug and chemical trades are the principal consumers. Oxides and fulminates are used in making paints and explosives respectively. Smaller amounts are used in electrical apparatus, gold (amalgamating) mills, scientific instruments (thermometers, barometers, and the like), and for mercury salts for drugs, etc. The mercury boiler may prove to be a large consumer.

Ores. Cinnabar is the principal economic mineral, but livingstonite and the native metal are also mined. The mercury minerals occur as veins, disseminations or masses of irregular form, not confined to any special type of rock, although igneous rocks are often found in the vicinity. The common gangue minerals are silica and calcite; pyrite or marcasite is usually, and bitumen often, present.

Production. World production is given in Table 104. The foreign deposits are of much higher grade than the domestic, hence competition is overwhelming. The principal domestic mines are in California and Texas.

Table 104. World production of mercury (metric tons) (*MI*)

Prices per flask of 76 lb. have been: 1929, $122.94; 1932, $58.30; 1937, $92.21; 1938, $77.11; 1942, $198.32.

Treatment. Mercury sulphides when heated to 500° to 600°C. decompose readily to yield mercury, which is in vapor form at this temperature. Because of this property, it is possible to drive off mercury vapor from mercury ores after relatively coarse crushing (<1 1/2- or 2-in.), the degree of comminution necessary depending upon the porosity of the gangue. Garbella and Thom (*Tref 10/40*) report a sizing-assay test on calcine as follows: 2∼1/2-in., 0.55% Hg; 1/2∼1/4-in., 0.10%; 1/4-in.∼8-m., 0.05%; <8-m., 0.06%.

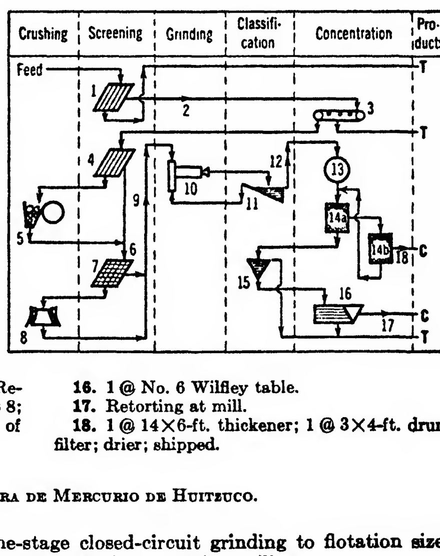
Experience has shown that ores carrying as little as 0.25% Hg can be roasted directly in rotary kilns more economically than by concentrating first and roasting concentrate. This is due to the fact that cinnabar is so friable that after severing it is too fine for gravity concentration, while flotation concentrate, although easy to make, dusts badly in the furnace. Friability of mercury minerals is, however, of practical benefit in beneficiation, in that substantial concentration is effected by crushing and screening. Thus Sulphur Bank low-grade run-of-mine ore showed 1.75 lb. Hg per ton in >2-in. size, 2.20 lb. in 2∼3/4-in., 4.25

lb. in $^3/_4$~$^1/_4$-in. and 11.5 lb. in <$^1/_4$-in. Since enrichment to a tenor well above 0.25% is readily effected by screening and rejecting coarse waste by hand picking, most treatment plants comprise initial rejection of waste by coarse sizing, with or without sorting of oversize; secondary sizing to 1 $^1/_2$- to 2-in., washing of the oversize to remove fines and to accentuate color, and sorting of good ore therefrom; crushing of the sorted material and furnacing of the crushed and original fines. Sorting thus may reduce the tonnage to be furnaced by 50% or more.

Cinnabar has a high specific gravity, and it is readily floatable; consequently low-grade ores in which the dissemination is too fine and uniform to permit rejection of waste by hand sorting are readily rough-concentrated, but the fine concentrate thus produced must be roasted by some more expensive method than simple passage through a rotary kiln. At SULPHUR BANK, even with crushing to 1-in. maximum, the amount of dust carried over from the kiln is so great that complicated de-dusting of the vapor must precede condensation thereof, and the dust so precipitated contains so much mercury that it must be floated and the concentrate retorted.

Exploradora de Mercurio de Huitzuco. Fig. 139 (*Tref 9/40, 10/40; A TP 896*).

Location: State of Guerrero, Mexico.
Ore: LIVINGSTONITE (mercury sulphantimonide) and cinnabar with stibnite, native sulphur, and pyrite in gypsum, limestone, dolomite, and chalcedony.
Capacity: 160 tons per 24 hr.
Assays: Feed: Hg 0.24%, Sb 0.96%; concentrate (shipped): Hg, 7 to 11%, Sb, 25 to 30%.
Recovery: About 90% Hg.
Ratio of concentration: About 40 : 1.



Legend for Fig. 139:

1. 10-in. flat grizzly; oversize waste picked out, ore sledged through.
2. 1 @ 40-ton bin.
3. 1 @ 30-in. picking belt.
4. 1 @ 3-in. grizzly.
5. 1 @ 10×20-in. jaw crusher.
6. Conveyor.

15. 1 @ 5-ft. desliming cone.
16. 1 @ No. 6 Wilfley table.
17. Retorting at mill.
18. 1 @ 14×6-ft. thickener; 1 @ 3×4-ft. drum filter; drier; shipped.

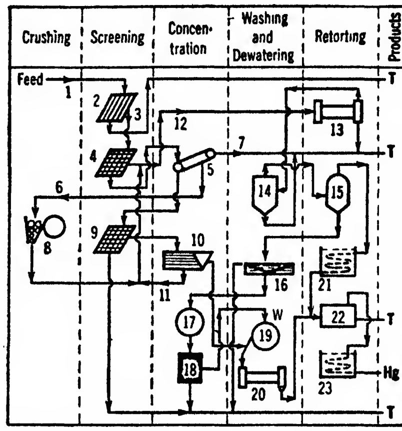
FIG. 139. EXPLORADORA DE MERCURIO DE HUITZUCO.

Summary. One-stage crushing and one-stage closed-circuit grinding to flotation size; simple rougher-cleaner flotation with tabling of sand in flotation tailing.

Sulphur Bank Syndicate. Fig. 140 (Worthen Bradley, *IC 6429*).

Location: Clearlake, Calif.
Ore: Cinnabar finely disseminated in altered basalt, with an average of 2% of elemental sulphur.
Capacity: 300 tons per 24 hr.
Assays: Feed, about 4.5 lb. Hg per ton of ore; rejected waste from hand sorting, 1.5 lb.; furnace feed, 8.3 lb.; kiln calcine, 0.4 lb.; cyclone dust, 2.5 lb.; flotation tailing, 2.0 lb.
Recovery: 85%.
Water: Pumped against 300-ft. lift from lake; 50-hp. motor; 75,000 gal. per 24 hr.
Power: 44.5 hp-hr. per ton.
Labor: Tons per man-shift, 3.4.
Costs (1930): Screening and sorting, $0.835 per ton of ore furnaced; furnace treatment, 1.709; flotation, 0.387; retorting, 0.177; condensing, 0.534; miscellaneous, 0.466; total, $4.108. Ratio of wet weight of ore mined to dry ore furnaced was 10 : 1, hence the total cost per ton mined was $0.41.

Summary. Primary rough rejection of waste as 9-in. grizzly oversize; secondary rejection by hand sorting of 9~1-in. washed crude; crude washings tabled to make high-grade for retorting and lower-grade for furnacing. All primary and all crushed undersize (except the washings) furnaced in a rotary kiln; rich condensate retorted together with table concentrate (as above) and flotation concentrate made from low-grade kiln condensate.



Legend for Fig. 140:

1. 2 @ 1-cyd. shovels from open pit; 8-cyd. trucks 1/4 mile.
2. Inclined grizzly, 70-lb. rails, 9-in. spacing.
3. Bin; 2-ton skips on inclined tram; 40-ton mill bin; apron feeder.
4. 1 @ 42-in. × 8-ft. trommel, 1-in. round holes.
5. 1 @ 36-in. × 40-ft. inclined picking belt with water sprays. About 20 tons per mo. picked off.
6. 1 @ 25-ton bin.
7. Stacking belt to waste dump.
8. 1 @ 10×20-in. jaw crusher, 2-in. open setting, run intermittently when bin (6) is full.
9. Shaking screen, 1/4-in. aperture, to remove chips.
10. Deister-Overstrom table. Concentrate assays about 1,000 lb. Hg per ton and amounts to about 90 lb. Hg per mo.; tailing assays about 6 lb. Hg per ton.
11. Storage ponds for dewatering and sun drying; hand shoveling to trucks to stockpile (12).
12. 1 @ 18-in. × 340-ft. belt conveyor; 1 @ 18-in. × 38-ft. belt conveyor; 1 @ 5,000-ton stockpile; dragline; 1 @ 18-in. × 48-ft. conveyor; 1 @ 7×15-in. × 47-ft. belt-bucket elevator; 1 @ 50-ton bin; 1 @ 30-in. Challenge feeder; 1 @ 18-in. × 65-ft. belt conveyor.
13. 1 @ 3-ft. 10-in. I.D. × 60-ft. rotary kiln, slope 1/2 in. per ft.; feed rate 1.8 dry tons per hr.; fired from feed end; exit gas temperature, 625° C. Oxygen supply is regulated so that there is no unburned sulphur in the exit gas, as such sulphur tends to recombine with mercury in the condensing system.
14. A dust-precipitating system comprising, in series: 1 @ 8×10×12-ft. rectangular steel chamber with a chain curtain; 12 @ 24-in. cyclones in 2 parallel series of 6; 1 Cottrell precipitator, 5×14×25 (high)-ft. Gas temperature leaving the cyclones is about 235° C.; dust load of the gas at the end of the system is about one ton per 24 hr.
15. Brick spray tower 7×6×26 (high)-ft. with water-sealed drawoff at bottom through which a low-grade mud is drawn continuously.
16. 2 settling tanks in series.
17. 1 @ 10×10-ft. Devereaux agitator, 25 r.p.m.
18. 1 @ 2-cell Kraut flotation machine run batch; treatment of a charge continues with recirculation of tailing until the grade of the froth on panning is low enough to indicate that it is permissible to discharge tailing. Feed averages 74 lb. Hg per ton, concentrate 600 lb., tailing 2 lb. Reagents are: Na Aerofloat, 0.054 lb. per ton; pine oil, 0.309 lb.; Barrett No. 4, 0.019 lb. Pulp density is 20% solids.
19. Batch-type vacuum filter.
20. Electrically heated batch-type drying pans; concentrate before drying is mixed with quicklime and sprinkled with water.
21. A condensing system comprising, in series: 1 vertical rectangular tank, 4×4 1/2×33 ft. with a water-cooled coil consisting of 360 @ 2 1/2-in. (O.D.) × 5-ft. pipes, inlet temp. 70° C., outlet temp. 41° C.; 1 @ 5×30-ft. and 1 @ 16×30-ft. vertical cylindrical wooden tanks in series; 1 @ 6 × 10 × 16 (high)-ft. Cottrell unit; 1 @ 20×30-ft. and 1 @ 16×30-ft. vertical cylindrical wooden tank in series; 2 @ 8 (diam.) × 16-ft. horizontal cylindrical wooden tanks in series. Provision is made for outside trickle-water cooling of the vertical tanks. By-pass arrangements permit clean-up (made monthly) without shutdown.
22. 3 standard D-type retorts (*Bul 222 USBM 144*).
23. Pipe condenser.

FIG. 140. SULPHUR BANK SYNDICATE.

Cloverdale Mining Co. Fig. 141 (G. H. Burr, *25 #6 MCJ 15*).

Location: Cloverdale, Calif.
Ore: Cinnabar as minute stringers and films along cracks in a highly fractured chert.
Capacity: 420 tons per 24 hr.
Assays: Feed, about 1 lb. Hg per ton; concentrate, 50% Hg.
Recovery: @ 50% in old mill by same method (*IC 6966*).
Cost: 15¢ per ton.

Summary. Screening with tumbling-scrubbing to concentrate mercury in <10-m. run-of-mine, followed by tabling and flotation of fines.

Legend for Fig. 141:

1. 3-ton trucks from open-cut mine to mill.
2. Grizzly, 6-in. apertures.
3. 500-ton bin; belt feeder.
4. 1 @ 5×5-ft. Price mill. This is a rotary scrubber with shell perforated with 3/4-in. rd. holes. Shell and lifters are manganese steel. 90% of cinnabar in feed is reduced to <10-m.
5. 24-in. conveyor.
6. Symons vibrating screen, 10-m. aperture.
7. Conveyor.
8. Rake classifier, operated for 65-m. overflow. Feed assays 4 to 5 lb. Hg per ton.
9. 320 tons out of 420 tons.
10. 2 Concenco shaking tables.
11. Thickener; diaphragm pump.
12. Conditioner.
13. Kraut flotation cells.
14. Dewatered and dried.
15. Retorted.
16. Added in small amounts to depress free S.

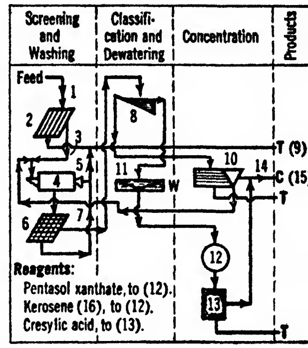


FIG. 141. CLOVERDALE MINING CO.

New Idria (*IC 6462*). Run-of-mine ore amounting to 600 t.p.d. is hand-sorted at >4-in. and at 4~1 1/2-in. with rejection of 60% as waste; all r.o.m. <1 1/2-in. plus the sorted ore crushed to this size is washed free of <60-m., the fines are floated, and the concentrate, joined to the washed ore, is furnaced in rotary kilns and condensed in a series of chambers. From 50 to 85% of the Hg produced is condensed finished in the first chamber; low-grade mud from succeeding chambers is floated, and flotation concentrate is returned to the kilns. Recovery is about 95%.

At BENEFICIADORA DE MERCURIO, San Alto, Zacatecas, Mex. (*Tref 7/42*), an ore assaying 0.67% Hg as cinnabar with a little metacinnabarite in a mixed quartz-carbonate gangue with some graphitic material is concentrated by rougher-scavenger flotation with two cleanings. Reagents are pine oil, ethyl xanthate, and AC 105. Concentrate, assaying 46.2% Hg, is retorted. Capacity is 50 t.p.d. Recovery, 95%; ratio of concentration, 72 : 1.

Small mills (*IC 6966*). At OAT HILL, near Middleton, Calif., an ore consisting of coarsely granular cinnabar in a soft gritty sandstone, assaying 3 to 5 lb. Hg per ton and not amenable to sorting, was treated at the rate of 1 t.p.h. in 1 @ 6×8-in. jaw crusher, 1 @ 16×10-in. rolls in closed circuit with a 6-m. vibrating screen, 1 Deister table which sent tailing to a desliming cone, the slimes of which were further tabled; concentrate from the tables, containing 50% Hg, was combined and retorted; recovery was about 85% and cost (1936) of milling and retorting was $1.12 per ton. At ESPERANZA MINE, near Cloverdale, ore comprising native mercury (80 parts) and cinnabar (20 parts) in soft sandstone, assaying 9 lb. Hg per ton, was milled by washing run-of-mine on a 2-deck shaking screen (3/16- and 1/16-in. holes), sorting out 50% reject from the upper screen, crushing >3/16-in. in jaw crusher and rolls and returning to the screen, discarding 3/16~1/16-in. and concentrating <1/16-in. on a long tom, bumping table, and carpet strakes in series; concentrate assaying 50% Hg was retorted; recovery was about 80%.

Hoeing pan is an iron pan about 6 ft. long, 3 ft. wide, and 4 1/2 in. deep, set on a slight incline, in which mercury mud and soot from the condensers is mixed with a little unslaked lime and hoed back and forth; the mercury is freed, coalesces, and flows down into a collecting pot under the lower end of the pan (*IC 6950*).

33. MOLYBDENUM

Uses. The principal use is in alloy steels. Those containing from 0.15 to 0.5% Mo are used extensively in automobile manufacture. Steels containing up to 3% Mo, usually containing also one or more of the following: chromium, nickel, cobalt, manganese, tungsten or vanadium, are used for permanent magnets, high-speed tools, stainless steels, etc. Molybdenum is also used as a substitute for platinum in jewelry, dental work, and gas-engine ignition. Molybdenum chemicals are used in dyeing, ceramics, and fire-proofing textiles. The pure metal is used in radio tubes, X-ray equipment, and electric-light bulbs.

Ores. The economic minerals are molybdenite, wulfenite, and molybdite. They occur as irregular masses or disseminations in crystalline rocks, frequently associated with bismuth and tungsten minerals, pyrite, pyrrhotite, and magnetite. Ores containing from 0.5% molybdenum upward may be of commercial grade.

Production. World production in 1921 was only 5.5 tons as compared with 18,000 tons in 1938. The increase is due to the development of the deposits at Climax, Colo., and to recovery of a by-product at UTAH, CHINO, MIAMI, and other copper mills. In 1938 the United States produced nearly 92% of the world output. World production is shown in Table 105.

a Includes Australia, Canada, Chosen.

Selling. See Art. 50.

Treatment. Wulfenite ores concentrate readily by gravity methods. Molybdenite does not respond to gravity concentration on account of its flaky character and ready flotation. Flotation, both from ores (CLIMAX) and from copper concentrates, is the present method of recovery.

The flowsheet of the molybdenum-recovery section at CHINO is given in Fig. 23. At MIAMI (*22 MMt 71*) bulk copper-molybdenum concentrate made in copper flotation is thickened, conditioned with lime, steamed for 2 hr. to remove the collector film from the copper minerals, filtered, and refloated with fuel oil and a frother, making a rough molybdenite froth concentrate and a copper tailing. The froth is recleaned 6 times and then leached with H_2SO_4; final concentrate assays 92% MoS_2. At UTAH (*22 MMt 71*) molybdenum flotation concentrate is graded up by roasting to oxidize the surface of the copper-sulphide particles selectively, the roasted material is floated first with a cationic collector to remove insoluble material, then with petroleum and a frother to raise molybdenite; the final tailing is enriched copper concentrate.

Climax Molybdenum Co. Fig. 142 (*Q* by E. J. Duggan, Mill Sup't; *153A 588; A TP 1675*).

Location: Climax, Colo.

Ore: Molybdenite (0.6%), pyrite (1 to 3%), chalcopyrite (0.02% Cu) in a gangue principally quartz and orthoclase with some sericites.

Capacity: 18,000 to 20,000 tons per 24 hr.

Assays: Feed; 0.6% MoS_2; concentrate, 90% MoS_2, 0.3% Cu, 0.4% Fe, 6% insol.; tailing, 0.05 to 0.07% MoS_2.

Recovery: 89%.

Ratio of concentration: 160 : 1.

Labor: American. Tons per man-shift, total, 84.

Running time: 96.5%. Repairs and ore shortage principal causes of loss.

Water: About one-third from mine, balance from reservoir. Mine water is gravity flow 1/2 mi. by pipe line; reservoir water pumped 4 mi. at consumption of 250 hp., 75% of water re-used. CONSUMPTION is 1.1 tons per ton of ore milled.

Building: Old, wood; new, steel. Floors, concrete and steel-grating. Millsite level. Heated.

Machinery handling: 12-, 15-, and 30-ton power cranes.

Power: Purchased. Comes 100 mi. at 33,000 volts. Motors, 440-volt, 60-cycle. CONSUMPTION: crushing, 2.6; grinding, 7.1; flotation, 2.4; classifying, 0.24; pumping, 0.34; water supply, 0.94; concentrate handling, 1.6; miscellaneous, 0.31; total, 15.6 hp-hr. per ton of ore.

Transportation: Narrow-gage railroad at mill. Ore comes 1/2 mi. by electric train. Concentrate shipped in barrels and sacks various distances.

Tailing: Gravity flow, 6,000 ft. of 18-in. wood-stave pipe in 3 sections as follows: 3,000 ft. at 0.3% grade, thence to a 45-ft. standpipe and 2,000 ft. on 0.1% grade, thence to a 30-ft. standpipe and 1,000 ft. level. Standpipes never run full. Head required ranges from an average gradient of 0.6% to 1.2%, depending on tonnage, particle, size and dilution. For further detail see Sec. 18, Art. 16.

Summary. Crushing from run-of-mine to <1/2-in. in 3 stages by jaw crusher, standard cone, and short-head cone, with circuit closed on the short-head by screens, but <1/2-in. material from the jaw-crusher product bled off immediately. Grinding to 28 *mog* for flotation is done in one stage with 9-ft. ball mills. All-flotation concentration, in which the primary stage scalps out a rough concentrate and discharges <28-m. tailing by a rougher-scavenger routing. Rough concentrate is reground and retreated on a rougher-scavenger flow, which discharges tailing and makes an intermediate concentrate that is reground, roughed, and scavenged to a tailing and then cleaned three times with the usual counter-flows of cleaner tailings. Cyanide, with or without lime, is added in various of the grinding and conditioning steps to depress iron and copper sulphides, and pebbles are used in the regrinding to keep out metallic iron. Approximately 99.5% of the pyrite and 95% of the chalcopyrite are finally eliminated. Recovery increases rapidly with increase in hydrocarbon up to about 0.6 lb. per ton, but a dispersing agent (ARCTIC SYNTEX M, a sulphated monoglyceride) is required for effective dispersion, particularly in cold pulps.

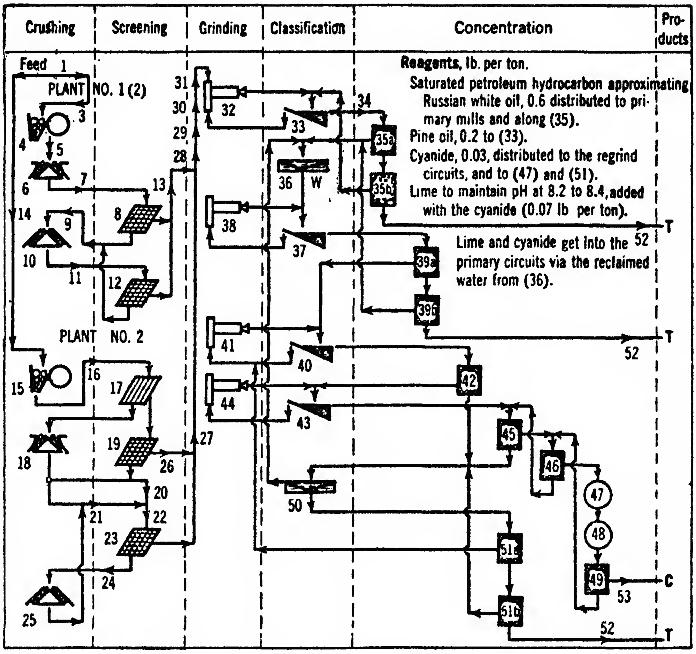

FIG. 142. CLIMAX MOLYBDENUM CO.

Legend for Fig. 142:

1. 10-ton Granby side-dump cars from mine. R.o.m. is split between two crushing plants.
2 5,000-ton capacity; old plant, used only during periods of peak capacity.
3 1 @ 500-ton bin; 1 Ross chain feeder, 15-hp. motor.
4. 1 @ 48×60-in. Buchanan jaw crusher, 9-in. open setting, 130 r.p.m., 300-hp. motor. *b*
5. 1 @ 48-in.×58-ft. pan conveyor (18 ft. horizontal, 40 ft. sloping for a 19-ft. rise), 60 f.p.m., 10-hp. motor.
6. 1 @ 7-ft. standard cone crusher, 1 1/2-in. set, 235 gyr.p.m., 300-hp. motor. *b*
7. 1 conveyor (item 7, Table 106); 1 surge bin; 4 belt feeders (item 7A, Table 106).
8. 4 @ 4×8-ft. Symons JK Rod-deck screens, 3/16-in. rod, 5/16×7-in. openings, 1,325 @ 3/8-in. s.p.m., 7 1/2-hp. motors.
9. 2 conveyors (items 9 and 9A, Table 106).
10. 2 @ 7-ft. short-head cone crushers, 1/4-in. set, 230 gyr.p.m., 300-hp. motors. *b*
11 2 conveyors in series (items 11 and 11A, Table 106).
12. 2 @ 5×8-ft. Symons JK Rod-deck screens, as (8).
13. 2 conveyors in parallel (items 13 and 13A, Table 106); 1 conveyor (item 13B, Table 106) with Merrick weightometer; 1 conveyor (item 13C, Table 106).
14. 2 @ 800-ton bins; 2 @ 6-chain Ross feeders, 3-in. chain, 15-hp. motors.
15. 2 crushers as (4) in parallel. 482 t.p.h. each. *b*
16. 2 @ 48-in.×13 1/2-ft. pan conveyors, level, 26 f.p.m., 10-hp. motors; 2 conveyors in series (items 16 and 16A, Table 106), the second with a magnetic iron detector and magnetic head pulley. The detector stops the conveyors when steel passes under it; it is much more effective than the magnetic head pulleys or overhead magnets.
17. 1 @ 6×6-ft. Robins Gyrex with grizzly cover, 1 1/4-in. spaces, 10-hp. motor.
18. 2 @ 7-ft. standard cone crushers, 1 1/2-in. set, 235 gyr.p.m., 300-hp. motors, 458 t.p.h. each. *b*
19 1 @ 6×12-ft. Gyrex screen, 1/2×3-in. aperture, 10-hp. motor.
20. 1 conveyor (item 20, Table 106).
21. From cone No. 2, 1 conveyor (item 21, Table 106).
22. 2 conveyors in series (items 22 and 22A, Table 106), the second with tripper; 1 @ 1,500-ton surge bin; 24 belt feeders (item 22B, Table 106).
23. 24 screens in parallel: 9 @ 5×10-ft. Gyrex, 5/16×4-in. aperture, 19° slope, 1,000 @ 1/4-in. s.p.m., 7 1/2-hp. motor; 2 @ 4×8-ft. Symons, as (8), 6° slope; 12 @ 4×7-ft. Jeffrey-Traylor, 5/16×1-in. aperture, 25° slope, 1/16-in. stroke; 1 @ 4×8-ft. low-head, 5/16×4 1/4-in. aperture, 1,100 @ 1/2-in. s.p.m., level, 5-hp. motor. Only the Rod-deck screens are free from blinding on wet ore.
24. 5 belt feeders (item 24, Table 106).
25. 5 @ 7-ft. short-head cones, as (10), 489 t.p.h., each, *b* including circulating load, 176 t.p.h. each new feed.

b Consumption of manganese steel liners in jaw crushers and cones totals 0.18 lb. per ton.

Legend for Fig. 142—Continued:

26. 1 conveyor (item 26, Table 106).

27. 2 conveyors in series (items 27 and 27A, Table 106), the second with a Merrick weightometer; 1 sampler, 1% cut.

28. 1 conveyor (item 28, Table 106), with tripper; 1 @ 15×53×28(high)-ft. rectangular wooden bin and 7 @ 35(diam.)×35-ft. 1,200-ton steel bins; material is 7% >3/8-in., 34% <10-m.

Table 106. Belt conveyors at Climax

29. Dust collection: All machines and conveyor transfer points are sufficiently enclosed to permit maintenance of a slight negative pressure; water sprays are installed at all transfer points. Fans in No. 2 crushing plant are: 1 @ 40,000-cu. ft. per min. Sturtevant Silent-vane exhauster, 1,088 r.p.m., 6 1/2-in. static pressure at 11,500-ft. alt., 50-hp. motor; 1 @ 3 7/8-in. Clarage, 34,000 cu. ft. per min., 662 r.p.m., 1 1/2-in. static pressure, 15-hp. motor; 1 Sturtevant Planovane exhauster, 12,600 cu. ft. per min., 789 r.p.m., 2 1/2-in. static pressure, 15-hp. motor; 4 @ 42-in. Sturtevant propeller wall fans, 14,500 cu. ft. per min. each, 480 r.p.m., 3/4-hp. motors for supplying fresh outside air. Fans in conveyor galleries are: 1 Sturtevant Rexvane, 2,650 cu. ft. per min., 2,462 r.p.m., 2-in. static pressure, 2-hp. motor; 2, same make, 2,970 cu. ft. per min., 2,180 r.p.m. A vacuum cleaning plant is used to clean floors and walls. All dust-laden air is passed through wet and dry Cyclones and canvas filters for dust recovery.

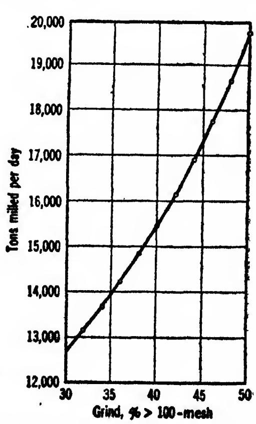

FIG. 143. Daily tonnage *vs.* fineness of grind at CLIMAX.

30. Primary concentrating plant comprises 7 substantially identical 1,850-ton sections (items 31 to 35) as follows, and one old section, similar in principle but differing in detail, used only under peak-load conditions.

31. 1 @ 36-in.×29-ft. belt feeder, 41 f.p.m.; 1 Fairbanks-Morse conveyor scale.

32. 1 @ 9×8-ft. Marcy grate-type ball mill, 20 r.p.m., 450-hp. motor, herringbone drive. Converted from 9×9-ft. overflow type with an increase of 18% in capacity to the same *mog* (28-m.). 3/4-in. grate openings (*vs.* 3/8-in.) necessary to maintain flow. 80 t.p.h. each. Effect of *mog* on capacity of primary-grinding section is shown in Fig. 143. Shiplap liners (chrome-molybdenum cast steel) substituted for rail-cement to gain diameter and reduce relining time. 2-in. gain in diameter increased capacity 5%. Relining time is 6 hr. Speeds of 17 to 22 r.p.m. (66 to 84% of critical) have been tried. Tonnage increased with speed, but not in proportion; liner wear (0.20 lb. per ton) was less at the lower speeds; ball consumption (1.1 lb. per ton) was not affected; 20 r.p.m., with grates, loads motors to capacity. 3-in. forged-steel balls with 0.2 to 0.3% Mo; this size is best of the range 2- to 4 1/2-in.; forged steel cheaper than cast balls at Climax; alloying with Mo decreased wear 15 to 20%.

33. 1 @ 78-in. Akins duplex high-weir classifier, 2 1/2 r.p.m., 3 1/2 in. per ft., 15-hp. motor, 400% circulating load; overflow, 45% solids, 60% <100-m.

34. 1 revolving chip screen with spiral discharge, 18-in. aperture, 8 r.p.m.; 2 @ 6-in. Wilfley pumps.

Legend for Fig. 142—Continued:

35. 3 @ 13-cell Weinig machines in series; a = 1 to 6 or 10. Series arrangement *vs.* 3 parallel units increased recovery about 1%. 35 cu. ft. per min. per spindle, 1 1/2-lb. pressure; conc. 12 to 20% MoS_2, less than half of which is free.
36. 1 @ 125-ft. thickener, 10 m.p.r., 5-hp. motor, overflow to mill water supply.
37. 1 @ 8×27-ft. heavy-duty rake classifier, 10 s.p.m., and 1 @ 48-in. Akins submerged-spiral classifier, 1.5 r.p.m., 2 3/4 in. per ft., in parallel; either or both used.
38. 2 @ 5×20-ft. Marcy tube mills, 25 r.p.m., 200-hp. motors, charged with 1-in. steel balls and rejects from the 9×8-ft. mills.
39. 2 @ 24-cell 36-in. Weinig flotation machines in parallel, 300 r.p.m.; a = early cells.
40. 2 @ 48-in. Akins submerged-spiral classifiers, 1 1/2 r.p.m., 2 3/4-in. per ft. a
41. 2 @ 8×20-ft. Marcy pebble mills, 16 r.p.m., 200-hp. motors. a
42. 3 @ 4-cell 36-in. Weinig machines in parallel, 300 r.p.m.
43. 1 as (40). a
44. 1 as (41). a
45. 2 as (42) in parallel.
46. 2 as (45).
47. 1 @ 8-ft. Devereaux-type agitator.
48. 1 as (47).
49. 2 as (45).
50. 1 @ 35-ft. Denver tray thickener, 9.2 r.p.h.; 1 @ 35-ft. thickener, 9.2 r.p.h.
51. 1 @ 12-cell and 1 @ 8-cell 36-in. Weinig flotation machines in series; a = early cells.
52. 18-in. wood-stave pipe line to tailing dam; Sec. 18, Art. 16.
53. 1 @ 24- and 2 @ 20-ft. thickeners. Overflow to mill water; 3 Oliver filters; 3 Lowden driers. Product less than 5% H_2O. Product shipped in 170-lb. paper-lined burlap sacks for domestic trade and in 30-gal. oak barrels (675-lb. capacity) for foreign shipment.

a Items 40, 43, and 41, 44 comprise three parallel closed circuits available as necessary for the feeds from items 39a and 42. Pebbles used in preference to steel because iron (or the soluble oxidation products) in the pulp reduces floatability of molybdenite.

This flowsheet represents a double application of the principle of roughing out tailing at relatively coarse sizes from an ore that must be ground to 270 *mog* in order to make the grade of concentrate required. Only about 40% of the molybdenite is free at 28 *mog*, 60% is free at 35 *mog*, 70% at 65 *mog*, 90% at 200, and 95% at 325.

At LE MOLYBDÈNE, district of Azegour, South Marrakesch, Morocco (*135 J 58*), a crude ore containing molybdenite and chalcopyrite is floated under conditions that depress the chalcopyrite initially. From a feed containing 0.05% Cu and 1.08% MoS_2, concentrate assaying 85.2% MoS_2 and 0.02% Cu is made; tailing assay is 0.10% MoS_2 and 0.06% Cu.

34. NICKEL

Uses. The principal use is as nickel steel, which is particularly strong, tough, and easily machined. Its greatest use in the past was for armor plate and projectiles. At present the automotive and steam-engineering industries take large amounts. Nickel has been largely used for plating other metals where corrosion is to be resisted, but is now largely displaced by chromium. A new important use is in PERMALLOY, used in the manufacture of ocean cable for high-speed transmission.

Ores. The economic minerals are niccolite, millerite, nickeliferous pyrrhotite, pentlandite, garnierite. The two most important deposits of the world are at Sudbury, Ontario, Canada, and on the island of New Caledonia. At Sudbury the ore consists of enormous masses of nickeliferous pyrrhotite segregated at the bottom of a quartz-diorite intrusion, and as scattered, irregular masses in the diorite. The ore contains 1 to 6% nickel and 1 to 2% copper together with Pt, Au, and Ag. The ore in New Caledonia is garnierite. No nickel mines are worked in the United States, although some few hundred tons of the metal are produced annually as a by-product in the smelting of other ores.

Production. The Sudbury district in Ontario is principal producer. Canadian production in thousands of metric tons has been as follows: 1918, 39.8; 1919, 18.6; 1929, 50.0; 1932, 37.8; 1935, 62.8; 1936, 77.1; 1937, 102.0. World production in 1937 was estimated as 113,000 tons. New Caledonia was next largest producer with 5,800 tons in 1937. Considerable nickel comes to market as "Monel Metal," the natural CuNi alloy formed by smelting ore from the Creighton mine of the International Nickel Co.

Prices. Electrolytic nickel in United States (including duty) has been 35¢ per lb. since 1929.

Treatment. The high-grade ores are smelted directly; low-grade ores are concentrated first, using flotation with or without antecedent magnetic concentration. For reduction of metal from concentrate see *Bray; Liddell; Hayward.*

International Nickel Co. Fig. 144 (*130 J 465; 58 CMJ 665*) *a*

Location: Copper Cliff, Ontario, Canada.

Ore: Chalcopyrite, pentlandite, and pyrrhotite cementing a breccia composed principally of granite, gneiss, quartzite, and graywacke.

Capacity: 8,000 tons per 24 hr.

Assays: Feed, 3.4% Cu, 1.7% Ni; (Au, Ag, Pt), $4 (at $20 gold); copper concentrate, 25% Cu, 1% Ni; nickel-iron concentrate, not available; tailing, 0.1% Cu, 0.25% Ni.

Recovery: Cu, 95%; Ni, 85%.

Ratio of concentration: 3.3 : 1.

Water: Comes from nearby lakes; gross CONSUMPTION, 1.1 tons per ton of ore; about 1/3 new.

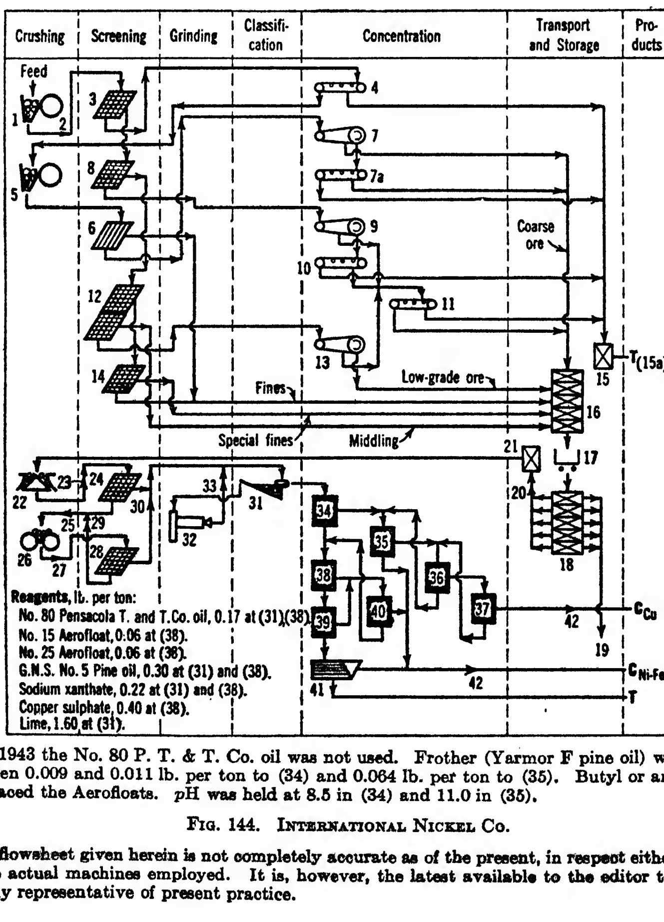
Power: Hydroelectric, company-generated; 2,300- and 550-volt motors. CONSUMPTION, 19.6 kw-hr. per ton.

Labor: 40 tons per man-shift.

Mill building: Level site. Steel and concrete frame; tile walls; roof of 2-in. matched board, covered with 1/2-in. wood-fiber board, tar paper and slate-surfaced asbestos felt. Steam-heated. Power cranes throughout. Dust-control system in crushing and screening plant; dust is immediately returned, wetted down, to the ore flow.

Tailing disposal: Tailing thickened in 2 @ 110-ft. thickeners and then pumped 17,000 ft. in three stages through 12-in. wood-stave pipe (crossing ridges 50 to 100 ft. above the pumps) to a tailing pond built and maintained in the usual fashion.

Summary. Four-stage crushing in two jaw crushers, standard cones and rolls from 26-in. r.o.m. to <3-m. Waste and direct-smelting nickel ore removed by magnet and hand picking at >1 1/2-in. Mill feed ground in one stage to 28 *mog*. Differential flotation to make copper and nickel-iron concentrates by successive rougher-cleaner routings with three cleanings for copper and one for nickel rough concentrates.



As of 1943 the No. 80 P. T. & T. Co. oil was not used. Frother (Yarmor F pine oil) was controlled to between 0.009 and 0.011 lb. per ton to (34) and 0.064 lb. per ton to (35). Butyl or amyl xanthate had replaced the Aerofloats. *p*H was held at 8.5 in (34) and 11.0 in (35).

FIG. 144. INTERNATIONAL NICKEL CO.

a The flowsheet given herein is not completely accurate as of the present, in respect either to tonnage or to the actual machines employed. It is, however, the latest available to the editor to use, and is essentially representative of present practice.

Legend for Fig. 144:

1. 30×42-in. and 36×48-in. jaw crushers set 5- and 6-in.; located at various points underground.
2. Shaft skips; head-frame pocket; rotary feeders.
3 2 @ 5×14-ft. trommels, 4 1/2- and 5 1/4-in. holes.
4. 2 @ 36-in.×90-ft. sorting belts, 35 f.p.m.
5. 2 @ 15×48-in. jaw crushers, 2 3/4-in. set.
6. 2 rail grizzlies, 3/4-in. spacing.
7. 2 pulley-type magnetic separators.
7a. 2 sorting belts.
8. 2 @ 4×8-ft. trommels, 2 1/2-in. holes.
9. 2 as (7).
10. 2 @ 36-in.×50-ft. sorting belts, 35 f.p.m.
11. 2 @ 36-in.×71-ft. sorting belts, 35 f.p.m.
12. 2 @ 4×8-ft. compound trommels, 1 1/2- and 7/8-in. apertures.
13. 2 as (7).
14. 4 Hum-mer screens, 0.129- and 0.190-in. apertures.
15. Sorted rock goes via bins and a conveyor to a 5 1/2-ft. standard cone set at 1 1/4-in. and thence by conveyor to a screen battery, the oversizes of which are sent over sorting belts with magnetic head pulleys from which a small amount of additional ore is scavenged. Reject is used for mine fill; screen undersize joins oversize of item (14).
15a. Amounts to about 25% of run-of-mine.
16. Separate bins for different products at mine.
17. Standard-gage rail haul; separate 60- and 80-ton gondola cars for different products.
18. 1 @ 10,000-ton steel receiving bin (7,000 tons live) at mill-smelter crushing plant, divided into 20 separate compartments (steam pipes, underneath to prevent freezing); 40 bottom chutes feeding to 4 traveling belt feeders; desired mixture of feeds drawn to (19) or (20). All <5-in. 10-man crews working two shifts are required for unloading; they dump a 5-car train in about 15 min. High-pyrrhotite ore cakes badly and blasting is necessary several times per year to maintain required live capacity.
19. Conveyor to smelter.

Crushing plant, capacity, 1,000 t.p.h.

20. 2 @ 36-in. belt conveyors in parallel, each with 1 @ 45-in. suspended pancake magnet. (These magnets are spaced sufficiently far from the belt to obviate removal of magnetic portions of ore.) 3 @ 36-in. belt conveyors in series; 1 @ 36-in. S-A motor-driven traveling tripper. 7 pickers per shift remove 25 to 30 tons of wood per 24 hr.; ash, of high nickel content, mixed with nickel concentrate from flotation.
21. 1 @ 1,200-ton bin; 3 steel-flight caterpillar feeders.
22. 3 @ 7-ft. standard cone crushers; set for 3/4- to 1-in. max. product; power consumption at 250 to 300 t.p.h. <5-in. feed, 120 hp. Feed rate (1937), 400 t.p.h. each. Manganese-steel bowls, 0.015 lb. per ton; lower mantles, 0.011 lb. per ton.
23. 2 @ 36-in. belt conveyors in series; 1 @ 36-in. traveling tripper; 1 @ 600-ton bin; 8 drum-type feeders.
24. 8 Traylor vibrating screens, aperture 0.16×4.31-in., about 20% undersize. Stainless-steel cloth.
25. 2 @ 36-in. inclined belt conveyors in series, with 22-in. pancake magnet; 1 @ 36-in. traveling tripper; 2 @ 450-ton bins; 2 drum-type feeders.
26. 5 @ 78×18-in. Traylor rolls (Ajo-type), set 3/16-in., 103 r.p.m., 2 @ 200-hp. motors each set. Circulating load about 200%. Feed rate 275 t.p.h. each. Forged chrome-nickel shells, 0.107 lb. per ton.
27. 2 @ 48-in. inclined belt conveyors in series; 1 @ 48-in. traveling tripper; 1 @ 1,500-ton bin; 24 drum-type feeders. Wood chips blown off belt by fishtail air jets to prevent accumulation in circuit.
28. 24 Jeffrey screens, 0.185×0.75-in. apertures; stainless steel.
29. 2 @ 48-in. inclined belt conveyors in series, with 45-in. pancake magnet; 1 @ 48-in. traveling tripper.
30. 7 belt conveyors; 2 Merrick weightometers; chain-and-bucket sampler; 36-in. traveling tripper; 14,000-ton A-bottom bin; 102 revolving feeders; 17 junction boxes.
31. 17 @ 12×28 1/2-ft. heavy-duty rake classifiers, 25 s.p.m. Feed: 1.2% >4-m., 39.2% <35-m.
32. 17 @ 6 1/2×12 1/2-ft. (inside) Marcy rod mills, 16 1/2 and 18 1/2 r.p.m., 200-hp. motors; 25 tons rods, 2 1/4-in. replacements; capacity, 500 tons per 24 hr. each.
33. 34 @ 3-in. Wilfley sand pumps, 1 active and 1 spare for each mill.
34. 30 @ 30-in.×20-ft. MacIntosh cells in 15 parallel 2-cell series, 9-in. rotors of punched sheet metal with perforated-rubber covers (0.01-in. punchings, 200 per sq. in.), 16 r.p.m., 2-hp. geared motors. Air pressure about 2 lb. Feed, 27 to 35% solids.
35. 32 as (34).
36. 32 @ 36-in.×12-ft. MacIntosh cells in parallel.
37. 32 as (36).
38. 36 as (34).
39. 8 as (35) in parallel.
40. 12 as (36).
41. 48 Deister Plat-O tables, 265 @ 15/16-in. s.p.m., 3-hp. individual motors. Installed to recover platinum as arsenide, which floats reluctantly.
42. Separate dewatering systems comprising rake classifiers sending overflow to thickeners, and thickener underflow with classifier rake products to filters; cake to bins and thence by conveyor to smelter. 80% reclaimed water. Passing thickener overflow through cascade machines to de-oil also removes some colloid.

Falconbridge Nickel Mines, Ltd. Fig. 145 (*Q* by R. C. Mott, Mill Sup't).

Location: Falconbridge, Ontario, Canada.
Ore: Nickeliferous pyrrhotite, 36.2%; chalcopyrite, 2.8; gangue: norite and chloritic greenstone, 61.
Capacity: 750 tons per 24 hr.
Assays: Feed, 1.0% Cu, 0.8% Ni; concentrate, 4.5% Cu, 3.5% Ni; tailing, 0.1% Ni.
Recovery: Cu, 95.9%; Ni, 90.1%.
Ratio of concentration: 4.7 : 1.
Labor: Canadian. Tons per man-shift: operating, 62; repairs, 250.
Running time: 97%. Repairs principal cause of loss.
Water: Lake, pumped 0.5 mi. About 5% re-used. Net CONSUMPTION, 1.75 tons per ton of ore milled.
Building: Steel-frame, brick-tile walls, Haydite roof, cement floors; slope of floor in wet part, 3/8 in. per ft. Level site. Heated.
Machinery handling: Hand crane in coarse-crushing, air-power cranes in fine-crushing and concentration sections.
Power: Hydroelectric. Motors, 550-volt, 60-cycle. 983 hp. installed, excluding crushing.
Transportation: Ore, 1/2 mi. by belt conveyors; concentrate, 300 ft. by belt conveyor to smelter. Railroad spur 3 mi. to main line.
Tailing: Pumped 400 ft. through wood-stave pipe to a natural storage basin.

Legend for Fig. 145:

1. 36×48-in. Traylor jaw crusher on 1,200-ft. level.
2. Underground pocket; skips; 1 @ 200-ton head-frame bin.
3. Vibrating grizzly feeder, 3-in.
4. 1 @ 48-in. picking belt. Waste rock (Cu, 0.32%; Ni, 0.21%), wood, and steel removed.
5. 1 @ 16-in. gyratory crusher, 3-in. open setting.
6. Belt conveyor, 400-ton surge bin, belt feeder, belt conveyor.
7. 2 @ 4×8-ft. Niagara 2-deck screens, 1 3/4- and 5/8-in. apertures.
8. 35-ton surge bins.
9. 1 @ 30×48-in. Dings pulley-type separator.
10. 1 as (9).
11 Vibrating screen, 6-m. cloth.
12. Alternatively to converter feed bins or to sintering bins.
13. This material runs 35 to 40% sulphides and will sinter alone, but is mixed with flotation concentrate (about 75% sulphides). This mixture sinters to a good cake. These fines do not respond well to the regular mill flotation treatment.
14. 2 @ 30×32-in. Dings pulley-type separators.
15. 1 @ 3×6-ft. vibrating screen, 2-in. aperture.
16. 40-ton surge bins.
17. 1 @ 4-ft. standard cone crusher, 3/4-in. closed setting.
18. 1 @ 5 1/2-ft. short-head cone crusher, 5/16-in. closed setting.
19. 1 @ 4×8-ft. 2-deck Niagara screen, 3/4- and 5/16-in. apertures.
20. 1 @ 30×48-in. Dings pulley-type separator.
21. Shuttle conveyor, 1,900-ton mill-feed bin, 24 Jeffrey-Traylor vibrating feeders, belt conveyor, shuttle conveyor, 1,100-ton ball-mill feed bin.
22. 1 @ 8-ft.×36-in. conical ball mill with Hardinge constant-weight feeder.
23. 1 @ 4×21-ft. Akins classifier.
24. 1 as (22).
25. 1 @ 6×25-ft. duplex rake classifier.
26. 1 as (22). About 15% sulphides, 4% >65-m., 54% <200-m.
27. 2 @ 16-cell No. 24 Denver Sub-A machines in parallel.
28. 1 as (27); *a* = cells 1 to 8.
29. Genter thickener.
30. 2 @ 9-ft. 16-frame Genter thickeners; stock tank; 2 @ 6-ft. 6-disk filters; cake, 12% moisture, to sinter bins.

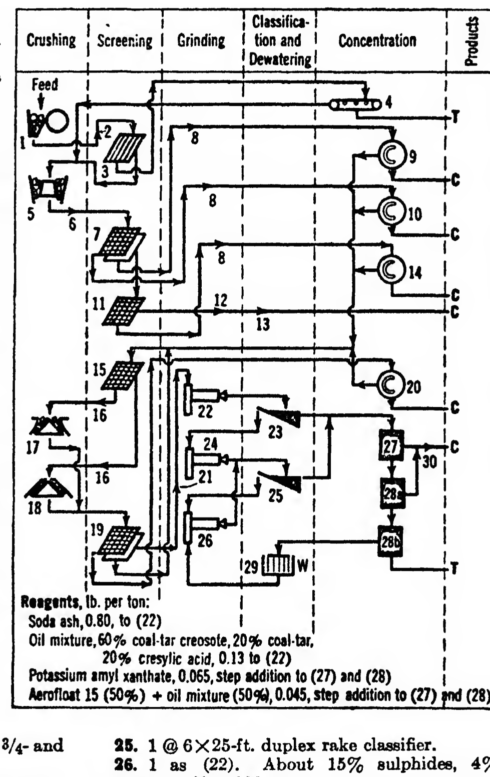


FIG. 145. FALCONBRIDGE NICKEL MINES

Summary. Crushing to 3-in., at which size concentration starts, in two stages, jaw and gyratory; middling further crushed to <5/16-in. ball-mill feed by a standard and a short-head cone in series, with circuit closed by a screen on the short-head. Grinding to

<48-m. flotation feed in three stages, the first two open- and the last closed-circuit. Magnetic concentration of closely sized products between 3-in. and 6-m.; flotation by a simple rougher-scavenger flow with regrind of scavenger middling.

No attempt is made to separate nickel minerals from the other metallic minerals. The endeavor is to save sulphides. Enough gangue is left in to give a good furnace charge. Blast-furnace smelting produces low-grade Cu-Ni matte, which is treated in converters and converter product is refined.

35. OSMIRIDIUM (OR IRIDOSMINE)

Uses. Principally as a hardening alloy for platinum, in same manner and for the same purposes as iridium. The alloy in its natural state is employed for fountain-pen points, for which purpose the granular Tasmanian product is preferred.

Osmiridium is a natural alloy ranging from 40 to 77% Ir and 20 to 50% Os (actual proportions given below), occurring in brittle hexagonal crystals or flattened grains. Color ranges from dark gray with bronzy sheen in the varieties highest in osmium, to brilliant tin-white in the high-Ir varieties. Sp. gr., 19 to 21; hardness, 6 to 7.

Occurrence. A frequent constituent of crude platinum, constituting 15 to 20% in the alluvial product of Colombia (where it also occurs—in the Choco district—associated with palladium and rhodium in quartz veins traversing granite, an unusual occurrence for platinum metal). Alluvial platinum from the Fifield district, N.S.W., carries 9.3% Os-Ir; that from Tulameen River, B. C., 10.5%; and that from Goodnews Bay, Alaska, up to 3.9% Os, in conjunction with 22% Ir. Osmiridium of this nature is recovered and reported as such by platinum refiners; it is possible that the two metals are not always actually and exclusively alloyed with each other. Osmiridium occurs in some of the Transvaal gold ores, more abundantly in the East Rand (and particularly in the Main Reef Leader) than in Central or West Rand.

The product, obtained by a preliminary pass over blanket or corduroy tables before cyanidation, averages quite consistently, in %: Os, 30; Ir, 26.5; Ru, 13.6; Pt, 11; Au, 2.4; Rh, 0.5; balance, undetermined. At several localities in Tasmania, alluvial gravels are worked exclusively for their osmiridium, which is found also *in situ* in serpentine rocks of the Bald Hill district, near Waratah. Analysis of the Bald Hill alluvial product: Os, 57.1; Ir, 33.8; Ru, 8.2; Pd, 0.2; Au, 0.04; Pt, 0.4%.

Production. During 5 yr. (1935–1939) U. S. platinum refiners averaged 548 troy oz. of osmiridium per year, of which 75 to 80% was extracted from imported crude platinum metals. During those same years, the Transvaal averaged 5,638 oz., and Tasmania 315 oz. osmiridium per yr.

Prices. During 3 yr. (1937–1939) osmiridium imported by U. S. (8,011 oz.) had average value of $24.56 per oz. Tasmanian output of 1939 was valued at £17 14s. per oz.

Treatment. Panning or sluicing as for gold (Art. 20); note use of blanket tables on Rand, as above. For separation and recovery of the metals, see *76 A 602*.

Osmium

Uses. Has been employed for incandescent-lamp filaments (now obsolete). No important use for the isolated metal, but see *Osmiridium*.

Occurrence. Chiefly in the natural alloy osmiridium; also (and usually in conjunction with Ir) in crude platinum; rarely among the platinum metals associated with copper-nickel ores.

Treatment. See *76 A 602*.

36. PALLADIUM

Uses. Alloyed with gold, as a substitute for platinum in dentistry, jewelry, and some chemical wares; plating on the graduated circles of surveying and astronomical instruments; as a solder for other and more refractory platinum metals; in finely divided form (palladium black) as catalyst for nitrogen fixation and contact sulphuric acid process.

Occurrence. Frequent component (0.5 to 1.5%) of alluvial platinum; sometimes also of alluvial gold. Important constituent of some copper-nickel ores; those of Sudbury, Ont., contain nearly as much Pd as Pt; the HAUT KATANGA copper refinery, Belgian Congo, recovers 4 or 5 times more Pd than Pt Palladium partially (9.4%) replaces platinum in cooperite—$Pt(AsS)_2$—in the sulphidic ores of the Bushveld deposits, Transvaal, and is the principal constituent (70.4%) of stibiopalladinite (Pd_3Sb) occurring most abundantly in

the Potgietersrust district of the same field. It occurs also (with Pt) in the Fe-Cu-Ni sulphides of the Bushveld ores and in the platinum metal set free by outcrop oxidation. The ratio of Pd to Pt is about 10% less in oxidized than in sulphide ores of the same deposit. Of the total output by the leading producer of platinum metals in the Rustenburg district in 1939, about one-fifth was palladium. Earlier (1928) operations at Potgietersrust yielded concentrates carrying about equal parts of Pd and Pt.

Table 107. Salient statistics on palladium, troy ounces

	1936	1937	1938	1939
Production:				
Canada *a*	103,671	119,829	130,893	135,402
Belgian Congo	12,571	12,507	1,575	....

Miscellaneous	859	55	35	540
	45,539	69,570	35,073	51,406

a Metal other than platinum—mainly palladium; separated and refined at Acton, England, and Kristiansand, Norway.

b By refiners, mainly of gold and copper from materials of which 75 to 80% is imported.

c Estimated on basis that palladium is 18% of combined platinum-palladium production. See Table 108.

Production and consumption. See Table 107.

Prices. Palladium was quoted at average of $23.21 per troy oz. in 1937–1938, and at $23.25 in 1939; price is much more stable than that of platinum or iridium.

Treatment. Concentration from alluvial deposits, by panning, sluicing, dredging, etc., as for gold (Art. 20). In the refining of blister copper, Pd follows Pt, Au, Ag, etc., into the anode sludge, and remains with Au and Pt after electrolytic parting of Ag from the doré metal. For subsequent separation and recovery, see *76 A 602*. For treatment of the Bushveld Pt-Pd ores, see Art. 31.

37. PLATINUM

Uses for the pure metal are restricted (by its softness) mainly to chemical ware, the winding of high-temperature resistance furnaces, and such parts of jewelry as require the setting of stones. For almost all other purposes, platinum alloys with Pd, Ir, Os, Rh, Au, Ag, Cu, Ni, and several other base metals are either more serviceable or can be substituted. The alloys are used principally in jewelry and in dental structures. Platinum black, usually supported on other and more bulky material, forms an effective catalyzer in many chemical manufacturing processes. Of recent years, owing to governmental confiscation of gold, there has been considerable hoarding of platinum as a hedge against inflation.

Ores. The economic mineral is metallic platinum, usually alloyed with one or more of the elements iron, iridium, rhodium, palladium, osmium, ruthenium, copper and gold; it may comprise as little as 75% of clean Pt concentrate. It has usually been recovered from placer deposits near areas of basic igneous rocks—peridotites, pyroxenites, dunites, and serpentine. Gravels that carry platinum are usually rich in chromite and olivine. Much recent production has come from the Ni-Cu ores of the Frood mine at Sudbury and from a primary deposit in dunite in South Africa. In these deposits the platinum occurs both as sperrylite ($PtAs_2$) and as a molecular constituent of pyrrhotite or other base sulphide; cooperite—substantially $Pt(AsS)_2$ with some replacement of Pt by Pd—is a constituent of the Transvaal sulphide ores, where platinum also enters the molecular composition of base sulphides.

Production and consumption. For many years, the world supply of platinum came almost exclusively from placer workings in Russia and Colombia, with minor by-product recoveries by gold and copper refiners. Since 1934, more than one-half of the total output has been derived from the nickeliferous pyrrhotite ores of the Sudbury, Ontario, district, in which platinum is accompanied by an almost equal proportion of palladium. The platiniferous matte produced by the International Nickel Co. is refined at Acton, England; that of Falconbridge Nickel Mines was refined at Kristiansand, Norway. The ores of these two companies, as mined, yield eventually about 0.047 oz. Pt + Pd per ton. Since 1930, the unique deposits at Rustenburg, Lydenburg, and Potgietersrust, in the Bushveld district, Transvaal, have produced important and increasing amounts of platinum accompanied by about one-fourth its weight of palladium. At Rustenburg, ores to a stoping width of 30 in. average 0.3 oz. Pt + Pd per ton. In the United States, the only important output of alluvial platinum is produced by dredges in the Goodnews Bay district, Alaska. See Table 108.

Table 108. World production of platinum (in ounces troy) (*MI*)

a Includes Australia, Japan, New Zealand, Panama, Papua, Sierra Leone. *c* Estimated.
b Not available. *d* Exports.

Prices. Average prices for refined platinum were (per troy oz.): \$46.84 in 1937; \$33.83 in 1938; \$36 in 1939.

Treatment. Alluvial platinum is recovered by sluicing or dredging, as for gold (Art. 20, 21). When it occurs with gold, platinum remains in the black-sand residues of the amalgamating devices and is recovered either by magnetic elimination of magnetite, etc., or by amalgamation with addition of an activator such as sodium amalgam. From Fe-Cu-Ni mattes, platinum is recovered by roasting, lixiviation of the soluble components, and reconcentration in a Pt-rich matte. For refining methods, see *76 A 602*.

Early methods for concentrating the oxidized ores of the Bushveld, in which platinum occurred in the free state, included stamp- and ball-milling, with special provisions for trapping metallics between stages, concentration on riffled tables, with redressing of middlings, and passing of fine tailings over corduroy tables (*29 JCM 157*). Concentrates down to 20-m. were redressed on tables and by hand and finally cleaned to 82% Pt by sulphuric and nitric acids. Fine concentrates were treated in an amalgamation barrel with addition of zinc amalgam, mercury, sulphuric acid, and copper sulphate, followed by acid treatment and retorting. By such process, ONVERWACHT PLATINUM, LTD., during 1928, milled monthly about 2,200 tons of ore averaging 6 dwt. Pt per ton, with over-all recovery of 84%. Sulphide ores yield a flotation concentrate containing 6 to 8 oz. Pt per ton, which is matted and rematted to about 25.5% Ni, 15.5% Cu, and 65 oz. Pt. After roasting, a leach with sulphuric acid leaves a residue from which, upon further smelting, a product at 60% Pt is obtained, with over-all recovery of 85%.

38. RADIUM

Uses. In therapeutics, particularly for treatment of cancer. In luminous paints, of which zinc sulphide is usually the major component. For inspection of metallic castings and welds; method is said to have some advantages over X-ray for this purpose.

Occurrence. Invariably associated with uranium, in nearly constant proportion 1 Ra to 3,400,000 U. Chief commercial source is pitchblende, an impure oxide of uranium; occurs also in carnotite (Art. 48), in the secondary minerals derived from pitchblende, and in several of the rare-earth minerals. At LUISWISHI and KASALO, Belgian Congo, pitchblende occurs in narrow, irregular veins in dolomite and shale; it is mined in open cuts and hand-sorted to a product (treated at Oolen, Belgium) which has contained up to 60% U_3O_8 and yielded 1 gm. Ra from 10 tons; in 1928, it required 30 to 40 tons of concentrate to yield 1 gm. Ra. In the historic ST. JOACHIMSTHAL mines, Czechoslovakia, pitchblende veins 6 to 20 in. wide traverse mica schist and limestone; concentrates formerly averaged 50% U and yielded 1 gm. Ra from 55 tons. In October, 1938, when absorbed by Germany, the mines were reported to have reserves containing over 300 gm. Ra; at that time, 36 to 38 tons of concentrate yielded 1 gm. Ra. Previously, Germany's only domestic source of radium was the mud collected (about 20 met. tons per yr.) from Bad Kreuzwach, carrying 1.75 mg. Ra per ton. At WILBERFORCE, Ontario, pitchblende occurs with fluorite and apatite in a pegmatite dike; a ton of ore yields concentrates containing 2.56 lb. U_3O_8, and 3,422 tons ore yield 1 gm. Ra. In the ELDORADO mines, at eastern end of Great Bear Lake, N. W. Terr., Canada, pitchblende and native silver occur in veins up to 21 in. wide, in granite; chief gangue minerals are quartz and Ca-Mg-Mn carbonates; base-metal sulphides are minor accessories (*139 #4 J 31*). In 1938, 41.5 tons mined ore made 1 ton concentrate, carrying 0.1203 gm. Ra.

Production. ST. JOACHIMSTHAL operations produced 59 gm. Ra from 1905 to 1935, and about 15 gm. (from about 560 tons of concentrated ore) in the next 3 yr.; the concession is now held by Auergesellschaft, of Berlin. Exports of concentrated uranium ores (estimated to contain 0.025 to 0.033 gm. Ra per ton) from Belgian Congo were none in 1933 and 1936, 465 tons in 1934–1935, 1,052 tons in 1937, but only 3 tons in 1938. Annual productive capacity at the Port Hope refinery of ELDORADO GOLD MINES, LTD., was increased in

1939 to 96 to 108 gm Ra; actual output: 15.54 gm. in 1936; 23.77 gm. in 1937; 67 gm. in 1938; 132 gm. (est.) in 1939. Radium contents of vanadium-uranium ores (mainly carnotite) mined in the United States is reported as 2.72 gm. in 1936; 3.14 gm. in 1937; 7.82 gm. in 1938; 8.96 gm. in 1939; actual Ra recovery not stated. During those years, such ores averaged 1.65 mg. Ra per short ton. Imports of radium salts by the United States were 38.75 gm. ($787,025) in 1938; and 78.63 gm. ($1,953,820) in 1939.

Prices. From mid-1936 to end of 1938, nominal price for radium salt of usual composition was $40 per mg.; in 1939, $27.50 per mg. for sales of 1 to 5 gm.

Treatment. For ore-dressing methods applied to the pitchblende-silver ores at Eldorado, see Art. 47; for treatment of carnotite ores, Art. 48. Of many proposed methods for the initial decomposition of pitchblende, only the following have been practiced industrially: (*a*) fusion with sodium sulphate (original Curie process); (*b*) roasting with sodium carbonate and nitrate (modified Curie); (*c*) leaching with hydrochloric acid (Cornish ores); (*d*) direct leaching with sulphuric acid (Belgian Congo ores); (*e*) oxidizing and chloridizing roasts, followed by sulphuric acid leaching (Eldorado ores). In all cases, the final concentrated product of this decomposition is a mixed barium-radium sulphate (Ba having been added en route) carrying 1 part Ra to 125,000 to 1,000,000 parts Ba. Extraction and condensation of radium from this sulphate mixture is by fractional crystallization of the chlorides or bromides (those of Ra being the less soluble), and follows the original Curie method. For the complete process for treatment of the ELDORADO concentrate see *44 CME 362*.

39. RUBIDIUM

Uses. Of the metal, in construction of photoelectric cells; of compounds, as reagents in microchemistry.

Occurrence. No mineral is definitely known in which rubidium is a major component. It occurs in minute amounts associated with lithium and caesium in a few minerals, and up to 3% in the lepidolites from some localities but is lacking in the lithia minerals amblygonite and spodumene. BOB INGERSOLL mine, Keystone, S. D., is the chief U. S. producer. Rubidium has also been extracted from carnallite.

40. SELENIUM

Uses. Photoelectric cells for purposes not demanding such instantaneous response as can be obtained from the potassium cell. Fireproofing of cotton or rubber cable insulations. Decolorizing of glass (contaminated with iron) or, in larger proportions (0.25%), for preparation of ruby glass and glazes; for these purposes sodium selenite is preferred. Vulcanizing of rubber. Improving machinability of copper and its alloys (*128 A 325*), and of stainless steels. In red to yellow pigments, with cadmium sulphide.

Occurrence. With native sulphur in some localities. Commonly with base-metal sulphide ores, present as a selenide (of which there are many) or as a molecular component of the sulphides, particularly of pyrite. Only industrial source is the fumes evolved by doré furnaces treating the anode sludge from electrolytic lead and copper refineries.

Production. In 5 yr. (1935–1939) the United States averaged 297,200 lb., and Canada (3 producers) 368,300 lb. per yr; refining of Rhodesian copper gave 4,100 lb. in 1938 and 1,300 lb. in 1939. United States imported (1935–1939) an average of 124,100 lb. annually, mainly from Canada. The potential supply exceeds the demand.

Prices. For several years prior to 1940, price of pulverized, 99 1/2% pure selenium varied but little from $1.75 per lb. It is also obtainable in cakes.

Treatment, as practiced by ONTARIO REFINING Co., Copper Cliff, Ont. (*A TP 908*). Selenium (and tellurium) is drawn from four sources: (*a*) niter slag from doré furnaces, containing sodium selenite and tellurite, both soluble in water to an alkaline solution; (*b*) "whiskers" from furnace flues, mainly selenium dioxide (55% Se) soluble in water to an acid solution; (*c*) acid solutions from scrubbers and wet Cottrell precipitators; after filtration, that from the scrubbers averages 21.8 gm. Se and 1 gm. Te per liter; that from the Cottrells averages 33.8 gm. Se and 2.4 gm. Te per liter; (*d*) cementation slime (mainly Te) precipitated (on copper sludge) from circulating leach liquors; this is roasted with NaOH and leached to an alkaline solution. These four solutions are mixed, are exactly neutralized by sulphuric acid or sodium carbonate, and are precipitated along with impurities. The selenium is precipitated in acid solution with SO_2, is filtered, washed, pulverized in a rod mill, dried, screened through 200-m., and marketed as a product assaying Se, 99.7; Te, 0.12; ash, 0.13; Cu, 0.001; Fe, 0.01%.

41. TANTALUM

Uses. Formerly in lamp filaments (now replaced by W); as a substitute for Pt when not required to resist HF, hot alkaline solutions, or high temperature in air; dental and surgical instruments; pen points; rayon spinnerets; rectifiers of alternating current; internal parts of vacuum tubes. Effect of Ta in ferrocolumbium when added to Cr-Ni steels is discussed in Art. 13. Implements fabricated from soft, malleable Ta are easily case-hardened. Metal-cutting tools composed of tantalum carbide in a matrix of Fe, Ni, or Co have some advantages over similar tools containing tungsten carbide.

Ores. Tantalite is the only commercial source of Ta; for composition and relation of this mineral to columbite (with which it is always associated) see Art. 13.

Production. Leading producer of low-Cb tantalite has been the Wodgina mine, Pilbarra field, Western Australia, where 20 to 30 tons of mineral averaging 65% Ta_2O_5, less than 10% Cb_2O_5, and notably free from Ti, Sn, and W, are recovered annually from shallow workings in soil adjacent to a pegmatite outcrop. Similar workings in the area south of Port Darwin, Nor. Terr., Australia, yield a small quantity of manganotantalite concentrates running 70% Ta_2O_5, 11% Cb_2O_5. Belgian Congo produced 122 tons of columbotantalite in 1937, 61 tons in 1938. Small yields have been recorded from Uganda and southwest Africa. United States imports of tantalum ores, short tons: 1937, 10.45; 1938, 20.85; 1939, 28.28; average value, $3,421 per short ton. Only important domestic production is from Black Hills, S. D.; output of concentrate was 8 tons in 1937, 18 tons in 1938, 340 lb. in 1939, mainly by Fansteel Mining Co., at Tinton. In 2 yr. of former activity (1928–1929) Tinton produced 28.5 tons of concentrate ranging from 38.7 to 57% Ta_2O_5 (*139 ℳ 11 J 39*).

Prices. Nominal prices for 60% concentrate in 1939 were $1.50 to $2.50 per lb. of contained Ta_2O_5. Average reported value for the 1937–1938 domestic output was $1,850 per short ton.

Treatment. Alluvial material, by panning, sluicing, etc., as for cassiterite (Art. 44). For lode ore, hand sorting, graded crushing of screened oversizes (tantalite being a brittle mineral), close sizing or classification, tabling of sands, and preferably separate treatment for slimes on buddles, canvas strakes, etc. High value of the concentrate justifies small-scale and carefully controlled operation. Ta and Cb are separated by a chemical process based on the differing solubilities of their double potassium fluorides. Ta metal in granular form is reduced electrolytically from fused K_2TaF_7; then sintered (in vacuo), pressed and swaged into cold-workable forms (*27 IEC 1166*).

Black Hills Tin Co. Fig. 146 (*IC 7084; 139 ℳ 11J 39*).

Location: Tinton, S. D.

Ore: Tantalite (@ 2.5 lb. Ta per ton), amblygonite, spodumene, feldspar, quartz.

Capacity: 32 t.p.d. Gyratory and cone on 1-shift basis; balance of mill on 2-shift.

Ratio of concentration: 860 : 1.

Labor: Direct mill labor: 4 men per day.

Water pumped 3/4 mi. against 500-ft. head, 30-hp. motor; 12,000 g.p.d.

Legend for Fig. 146:

1. 1-ton car about 30 ft. from headframe to sorting chute; about 50% rejected as waste by hand picking and grade thus raised from 2.5 to 5 lb. tantalum per ton; ore by 2 1/2-ton truck 1/2 mi. to mill feed chute; waste by same truck 300 ft. to dump.
2. Gyratory crusher, open setting about 1.5 in., 15-hp. motor.
3. 20-in.×40-ft. belt conveyor.
4. 5×5-ft. vibrating screen, 1-in. aperture, 1/2-hp. motor.
5. Cone crusher, 1/4-in. set, 30-hp. motor.
6. 10-ton bin; 1-ton car, 50 ft.; 25-ton bin; oscillating feeder; bucket elevator.
7. Vibrating screen, 1/2-in. aperture.
8. Small rolls.
9. Vibrating screen, 1/8-in. aperture.
10. Vibrating screen, 20-m.
11. 2 shaking tables.
12. Oil-fired drier.
13. Vibrating screen, 30-m.
14. Shaking table.
15. Drying pans. Sacked.
16. One shaking table fed with accumulated batches of material; a = >30-m., b = <30-m.
17. 2×2-ft. vibrating screen, 1/8-in. aperture.
18. Nest of 2×2-ft. vibrating screens: a = 20-m., b = 30-m., c = 48-m., d = 60-m.
19. One shaking table fed with accumulated batches of the different feeds indicated.
20. Final undersize, <60-m.

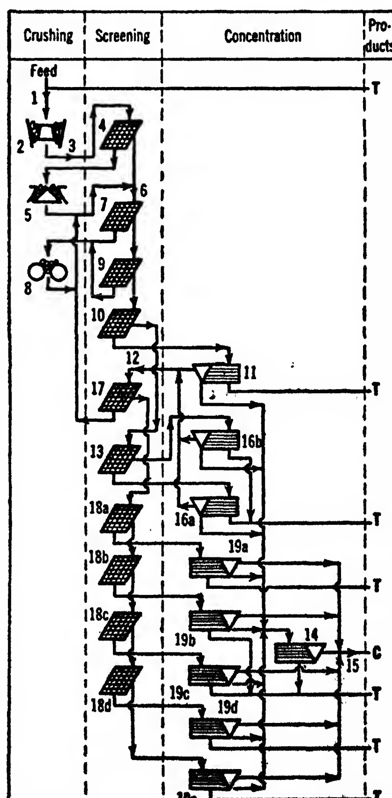

Fig. 146. Black Hills Tin Co.

Power generated at mill by Diesel engines; motors, 440-, 220-, and 110-volt, 3-phase, 60-cycle.
Tailing: Settled in a series of 3-brush dams and one large earth dam about 1/2 mi. below mill.
Costs per ton of ore milled (June, 1938): Primary and secondary crushing, $0.10; rolls and primary tables, $0.192; cleaning concentrates, $0.097; pumping, $0.053; tramming from crushing plant to concentrator, $0.031; general, $0.504; total, $0.977.

Summary. Crushing from head-size to $<^1/_8$-in. in three stages (gyratory, cone, rolls), the last in closed circuit with a screen. Concentration by rough tabling at three screen sizes and table cleaning of rough concentrate at five sizes.

42. TELLURIUM

Uses: Producing blue and brown colors in glass, pink on ceramics. In diethyltelluride, as an anti-knock addition to gasoline, but more expensive than tetraethyl lead. Improving machinability of copper and its alloys (*128 A 315, 325*), and substituted for sulphur in steel screw stock. In vulcanizing rubber, and as a hardening alloy for lead and tin.

Occurrence. Has been found native. Commonly as a telluride, those of Bi, Ni, Fe, Hg, Pb, and Cu being known, and, more importantly, those of Au and Ag, singly or combined. Only industrial source is the fumes from furnaces working on anode sludges from electrolytic copper refineries.

Production. In 5 yr. (1935–1939) U. S. averaged 36,550 lb., and Canada, 32,950 lb. per yr. Potential capacity greatly exceeds present demand.

Price, to 1940, was steady at $2; later at $1.75 per lb. Tellurium is available in cakes, sticks, and powder, 99% pure.

Treatment, as conducted by Ontario Refining Co., Copper Cliff, Ont. (*A TP 908*). For sources of Te and its separation from Se, see Art. 40. The impure Te filtered out of exactly neutral solution (in which Se remains) is dissolved with aqueous caustic soda and the base-metal hydroxides precipitated. Neutralization of the filtered solution of sodium tellurite with sulphuric acid precipitates TeO_2 contaminated with SiO_2 and Pb. The filtered and washed cake is redissolved in NaOH, avoiding excess, lead is precipitated with Na_2S and filtered out with the silica. The purified solution precipitates pure TeO_2 upon heating to 180° F. and exactly neutralizing with sulphuric acid. The washed and dried oxide is reduced with flour and borax in a covered crucible at dull-red heat, and the metal is cast into molds; average analysis: Te, 99.75; Se, 0.04%; Pb, trace.

43. THORIUM

Uses. The important use is in the manufacture of thorium nitrate for gas mantles, which are 99% thoria. Thoria is used as an industrial catalyst. Thorium salts are all radioactive. Thorium metal is alloyed with tungsten for electric-light and electron-emissive plates and filaments, and with aluminum and magnesium to improve casting properties. Praesodymium, neodymium, and lanthanum are next after cerium (Art. 10) and thorium in order of importance, the first two for special optical glasses, the last, with erbium, in cosmetics. Mesothorium, of which minute amounts are obtainable from monazite, is used as a substitute for radium.

Ores are beach placer and dune sands in which monazite (a phosphate of the cerium metals (Ce, La, Di) containing also from <1 to 18% ThO_2 and small amounts of Sa, Er, Yb, and other rare earth elements) occurs with other heavy minerals such as zircon, rutile, garnet, ilmenite, magnetite, and tourmaline and also, of course, with quartz, feldspars, and mica. Analyses are given in Table 109.

In British India certain small areas contained up to 46% monazite, but the commercial sands mined from 1906 to 1922 (before the ilmenite market was developed) averaged only 15 to 25%. Now, however, 2 to 5% monazite is contained in sands mined principally for ilmenite content. Originally the Brazilian sands were rich enough to ship as found; now they must be concentrated. In Malaya, monazite is associated with cassiterite; in Florida with ilmenite, rutile, and zircon; in the Carolinas with ilmenite, magnetite, rutile, garnet, hornblende, and gold; and in Idaho with gold, ilmenite, and zircon. In Ceylon, monazite constitutes only 8% of the heavy sands and ilmenite 75%. Monazite is a potential by-product in all placer operations.

Production. The principal producing countries are India and Brazil. World production has ranged from 100 to 7,000 tons annually. The principal domestic deposits are in North and South Carolina.

Selling. Usual specification is a minimum rare-earth oxide content of 57 to 60%. Price is a matter of bargaining with the buyer; range of *Engineering and Mining Journal* quotations, 1936–1939, was $60 to $75 per short ton of sand of minimum analysis.

Treatment consists in rough concentration to reject the lighter sands, followed by careful separation of the heavier sands by gravity concentration, or by electrostatic or

electromagnetic methods. Sluice concentrate contains 20 to 60% monazite. When this is dried and closely sized (20-, 50-, 80-, and 100-m.) and treated carefully, first by a low-intensity, then a Wetherill high-intensity separator, the products are: low-intensity magnet, magnetite; high-intensity: first pole, ilmenite, hematite; second pole, garnet, platinum, epidote, apatite, olivine, tourmaline; third pole, monazite with small amounts of zircon, rutile, epidote, etc.; fourth pole, fine grains of monazite; nonmagnetic: gold, zircon, rutile, quartz, feldspar, etc. The gold, zircon, and rutile can be separated from the tailing by shaking tables (*TP 110 USBM*: see also *Ladoo*). Considerable chemical treatment is required to separate the various metallic compounds from the sands.

Table 109. Analyses of monazite sands (*After IC 7233*)

Item	Percentage range			
	United States	Brazil	Malaya and Australia	India and Ceylon
ThO_2	1.2 to 7.0	1.1 to 10.0	3.4 to 8.4	7.9 to 10.8

b Ta_2O_5. *d* U_3O_8.

44. TIN

Uses. On account of its resistance to corrosion by air, water, and weak acids, tin surfaces are widely used where such corrosive action is to be resisted. Hence tin-plate, which is sheet iron covered with a thin layer of tin, is used for roofs, kitchen utensils, and containers for canned goods. Cooking utensils made of copper are tinned to prevent the formation of poisonous copper salts. Important alloys of tin are: soft solder, an alloy of tin and lead which has a lower melting point than either the tin or lead; bronze, bell metal, and speculum metal, principally copper and tin; Britannia metal, consisting of tin and antimony, with sometimes copper and zinc; bearing metal, and pewter. Lead-tin alloys are used for foil, collapsible tubes, and the like. Tin salts are used to weight silks.

Ores. The principal economic mineral is cassiterite. Stannite is relatively rare. The largest production comes from cassiterite gravels, but primary ores in which cassiterite and sulphides, with or without tungsten minerals, occur in veins are also important.

Table 110. World production of tin (thousands of long tons) (*MI*)

Selling. See Art. 50. Ten-year average PRICES, per lb. at New York have been: 1913–1922, 48.91¢; 1923–1932, 45.43¢; 1933–1942, 48.86¢. Yearly averages at New York: 1929, 45.19¢; 1932, 22.01¢; 1937, 54.24¢; 1938, 42.26¢; 1942, 52¢.

Production. The placer deposits of the Federated Malay States and of the Netherlands East Indies (Banka and Billiton) produce about 50%, and the lode deposits of Bolivia about 20% of the world's tin. World production figures are given in Table 110.

Treatment. Cassiterite placers are mined and treated by usual placer methods, but recovery is more difficult than that of gold, and clean-up of concentrate requires a more extensive plant; also jigs are used to a much greater extent. The Bolivian vein deposits are of several different varieties and degrees of complexity. The tin mineral is invariably cassiterite. In the simple oxidized ores the accompanying minerals are principally quartz, feldspars, and iron oxides, and separation is simple. The sulphide ores, frequently occurring in the same mines below the oxidized ores, contain, in addition to cassiterite and the gangue minerals, part or all of the following: pyrite, chalcopyrite, bornite, arsenopyrite, wolframite, bismuth minerals, silver minerals, galena, and sphalerite. Many of these ores are of high grade and the cassiterite occurs in relatively coarse particles, but the complexity of the ores makes concentration difficult and the inaccessibility of the district makes changes in methods slow to be effected. In Cornwall the ores are of low grade, are more or less complex, and the cassiterite is very finely dispersed.

Placer tin. The gravels are principally of low grade, representing tailing from previous placer operations on higher-grade gravels or low-grade ground that was passed over in the earlier work. Modern dredges can operate profitably on ground containing as little as 0.4 lb. cassiterite per cyd. (*126 J 1016*). The typical flow sheet, Fig. 147, comprises dis-

Legend for Fig. 147:

1. *Hopper:* This should have at least 30° minimum slope.

2. *Spill* from bucket line. Clay tines, comprising cast-steel arms with manganese-steel tips, are mounted on a horizontal shaft and are so positioned as to be engaged by the bucket lip, whereupon the further movement of the bucket forces them to follow the curve of the bucket back and gouge out the load; they work well and are practically foolproof (Eckhart, *50 MM 208*); they reduce spill by facilitating clean dumping.

3. *Screen:* This is almost invariably a large revolving screen, 10 ft. or greater in diameter by 60 ft. or more in length, weighing upward of 45 tons. Construction is like that of the screens on gold dredges (Art. 21) except that, since the Malay tin gravels usually contain much more clay than is found in gold placers, lifters and retarding rings are more common. Maximum impact from wash water is sought, and gained by large jets and a heavy flow of water; three rows of jets are recommended in order to keep the clay lumps subject to jet action for as great a part of the time spent in the screen as possible. The first section of the screen (10 to 20 ft.) is usually surrounded by imperforate plate, and thus comprises a typical drum-type washer. Apertures are from 1/4 in. to 1 in., depending upon the size of the cassiterite grains and the amount and character of clay. Screens are, in general, greatly over capacity from a screening standpoint; the great bulk of the screening is done in the first few feet of perforate surface. Apertures are usually smaller near the head end in order to aid distribution and hold back the smaller clay balls. Retarding rings aid disintegration but lower screening efficiency by increasing bed thickness. Slope is 1 to 1 1/2 in. per ft. 75 to 100-hp. motor. Drive is as on gold dredges. Rock chute is normally sloped 1 : 4, but 1 : 3 is not enough for sticky clay, which is best handled by an independent stacker fed by chute sloping 1 : 2. Discharge lip of the rock chute should not be higher than the tailing launder, if damage to the latter in swinging is to be avoided.

4. *Save-all grizzly,* positioned in ladder well. Aperture is 2- to 3-in. It should be so constructed that bars may be changed as readily as possible, since they are difficult of access.

5. *Save-all sluice.* This is usually made too steep for good recovery in the endeavor to prevent clogging by coarse feed. Access is difficult, hence pains should be taken to facilitate clean-ups.

6. *Rougher jigs.* Most modern tin dredges use jigs in this position, but riffled sluices are found in some of the older structures. Harz or Cooley types predominate, but recent boats use special placer types (Sec. 11, Arts. 7, 8, 11). Concentrate is made through the screen. Compartments are usually 3(wide)×4-ft., but are not stepped, rather the screen is placed on a continuous slope of 1 : 16. From 300 to 700 sq. ft. of jig screen surface is the usual allowance for roughing, depending upon digging capacity and percentage of oversize roughed out on screen (1). Eckhart (*loc. cit.*) gives 0.6 cyd. per hr. per sq. ft. of screen area as the maximum capacity for Harz types in this service. Three cells are usually sufficient, except for rich feeds. Screen, with 1/8 or 3/32×1/2-in. apertures, is woven or punched; slots usually run lengthwise. Usual speed is 110 r.p.m., but this is increased somewhat with heavy loading; stroke is varied to suit conditions. Means for ready adjustment of stroke and speed by the

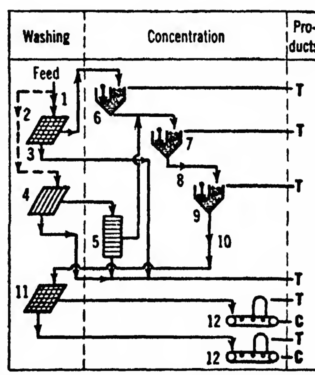

FIG. 147. Typical Malayan placer-tin flowsheet.

Legend for Fig. 147—Continued:

operator to compensate for changes in feed are recommended by some designers, but such practice proved bad except in the hands of the most skillful operators.

Bed material is commonly composed of hard hematite ore (Vallentine *39 IMM 130*), sp. gr. = 5.2; cassiterite bedding (sp. gr. = 6.9) is not satisfactory. In preparing the bed lump hematite, $^3/_4\sim^3/_{16}$-in., is tumbled to round off the corners; about 50 lb. per sq. ft. of screen area, making a bed about 2 $^1/_2$ in. thick, should be provided for roughing jigs. For cleaning jigs rounded material $^3/_8\sim^3/_{16}$-in. should be used, the weight necessary being about 34 lb. per sq. ft.

Feed was roughly sized or classified in early jig installations, but experience has shown that dewatering sufficiently to prevent an excessive rush of cross water is all the preparation that is necessary or desirable. Ample working space and good lighting should be provided. Variable feed rate must be anticipated and if digging capacity is to exceed normal roughing capacity, it will be well to install one or two spare jigs, even though this involves a slight increase in area of boat and height of upper tumbler.

Tin sluice (if used in this position in place of jigs) is 4 to 6 ft. wide, 60 to 300 ft. long; grade, 1 in 24 to 1 in 40, depending upon the amount of water used; unriffled, but with 3×2-in. stops which are placed across the bottom at 6- to 10-ft. intervals, and increased in height to 9 or 12 in. as concentrate builds up behind them. Cleaned up by careful shoveling-over in a stream of clear water. Crude concentrate sent to shed is 10 to 50% cassiterite.

7. *Cleaner jigs.* These are usually of the same type as the roughers; they should be 4-compartment to guard against tailing loss. Screen area provided is about 10 to 20% of the roughing area. Speed, about 180 to 190 s.p.m. The concentrate of these jigs is the final product made on the boat. Cleaner tailing is recirculated on some boats.

8. *Cleaning shed* is located on dredged-over or barren ground, as centrally as possible with respect to the area to be worked over by the dredge or dredges supplying it. Equipment and flowsheet vary according to the size of the operation and the nature of the concentrate.

9. *Recleaner jig.* This may be either mechanically or hand operated; if mechanical, it is frequently of pulsator type, since cleanliness of concentrate rather than high capacity is the primary objective. If a hand jig is employed, it is usually preceded by a sluice to rough out some tailing and to make a fine finished concentrate, leaving a middling containing the coarser cassiterite for jigging. Such a sluice is 10 to 12 ft. long, 9 to 10 in. deep, converging from 3 or 5 ft. in width at the head end to about 15 in. at the discharge end; water is supplied full width at the head end over a weir board 6 to 7 in. high; in operation a fairly strong stream of water is used at first while material is hoed to wash out the bulk of the sand, then the residue is washed with a weak stream and coarse concentrate is collected at the lower end, finally the residue is washed with a heavier stream and brushed upslope, yielding fine concentrate and middling.

10. *Drying.* This problem is simple; the tonnage is small, the product is relatively fine but is slime-free (see Sec. 17).

11. *Screen battery.* These screens are used to prepare for magnetic concentration to separate magnetite, ilmenite, etc., from the cassiterite. The number of screens and the types depend upon the tonnage to be treated, the size range of the concentrate, and the difficulty of the separation.

12. *Magnetic separation.* Low-intensity machines (Sec. 13, Arts. 4, 5) will remove magnetite. The amount of high-intensity work done depends on the minerals present and the premium for high-grade concentrate.

Water. When large amounts of clay are present in the gravel, the pond water will build up in consistency until it approaches that of a thick soup, whereupon the saving of fine tin substantially ceases, and circulating pumps are subjected to excessive wear. The remedy is, of course, to bleed off a sufficient quantity from the pond to prevent such a build-up; otherwise periodic pump-outs of the pond are necessary. In any case, pump-suction lines should take from near the pond surface, as far from the digging ladder and tail-sluice discharge as possible. If, as is usually the case, the amount of organic debris is high, a large intake screen must be used, so arranged as to facilitate cleaning.

Tailing disposal. The under-water angle of repose of fine tailing may be 10° or less; hence this material will spread out over a large area on the pond bottom and may run back under the boat far enough to reach the digging ladder, correspondingly decreasing the capacity of the boat for new feed. Hence the tailing launder should be extended as far as possible, or the fines separated from the coarser tailing and pumped a sufficient distance from the boat. A slope of 1 in 16 will normally maintain a free flow (Vallentine, *loc. cit.*). Rubber liners give longer service than steel.

Lost time may be anything up to 20% and monthly output will rarely exceed 60% of theoretical capacity.

Recovery probably never exceeds 90% and is usually nearer 75% of the tin in the bank. Losses occur in the form of coarse cassiterite, granular cassiterite adhering to clay balls, both of which pass out on the stacker; granular tin adhering to smaller clay balls that pass over the rough concentrators, fine tin that remains in suspension in the cross-flow over the roughers, and in the relatively high grade tailings made in the cleaning shed.

Concentrate assay is 70 to 76.5% Sn.

Cost (1934) at 4 dredges ranged from 5.6 to 8.8¢ per cyd. (*27 CEMR 319*).

integration in a revolving-screen washer, rejection of screen oversize as tailing, rough concentration of screen undersize on sluices or jigs, making a large bulk of low-grade concentrate, preliminary cleaning of concentrate in jigs, and final cleaning on jigs or shaking tables, or, in less modern plants, on film sizers (Sec. 11, Arts. 31, 32). Gravity concentrate,

containing magnetite, is dried, sized, and subjected to magnetic concentration. In dredging, the roughing and preliminary cleaning are done on the boat, the balance of the run-up in grade is done in the CLEANING SHED on shore. In designing, the size of the treatment equipment on the boat is determined by the capacity of the digging equipment, the maximum size of the cassiterite, and the percentage of oversize gravel. Since the latter may vary from 80% average to 30% or less average as between different deposits, the necessity for careful testing preliminary to design is apparent.

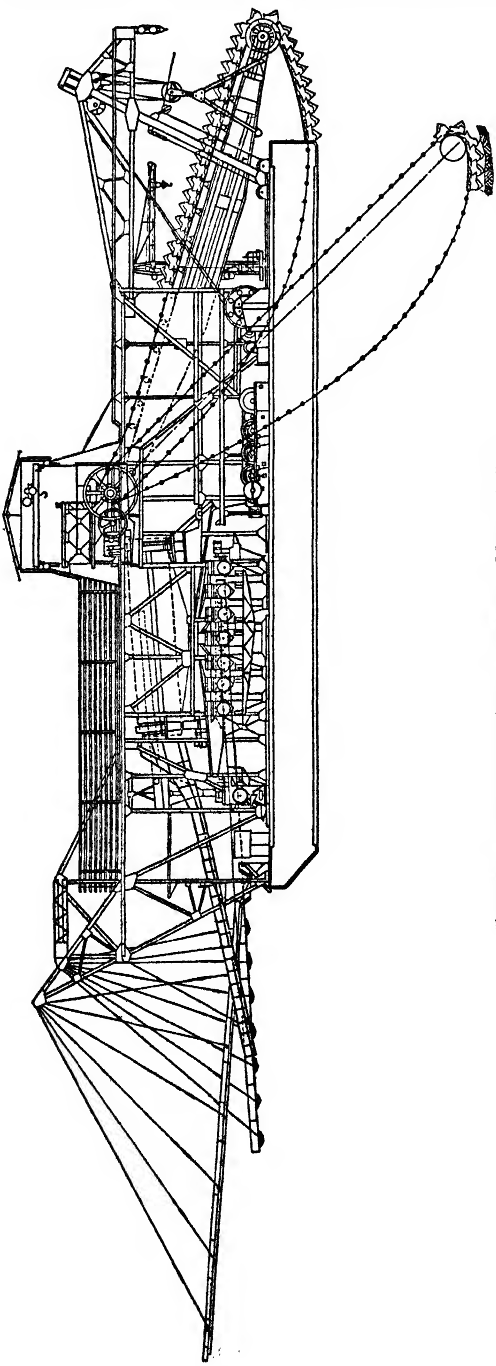

FIG. 148. Tin dredge at ANGLO ORIENTAL (MALAYA), LTD.

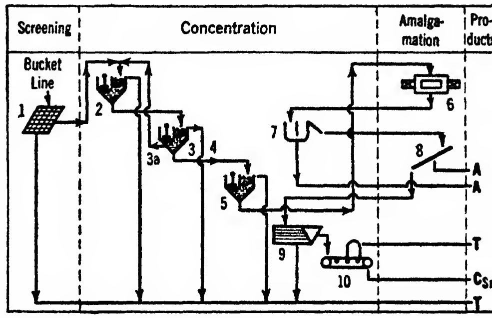
Anglo Oriental (Malaya), Ltd. (*Q*) operated five 18-cu. ft. dredges in the Kuala Lumpur district. These dredges had two parallel screens in the same housing stepped down in diameter from 8 1/4 to 7 3/4 ft. (in lieu of retarding rings), the length of perforated section being 35 ft. Apertures increased from 3/8-in. to 1/2-in. along the run; speed, 8 r.p.m.; water pressure on monitor jets, 30 lb. per sq. in. There were 10 @ 4-compartment Ruoss roughing jigs (Sec. 11, Art. 7) each side, rough concentrates going to 3 @ 4-compartment Ruoss cleaner jigs, making concentrate tailing, and a middling from the last three compartments, which was dewatered on the boat in a cone and then recleaned in a 4-compartment Ruoss jig; this made concentrate a middling from the last two compartments which circulated on the jig, and a final tailing. Boat concentrate assayed 10 to 30% Sn and was run up to 75% Sn in the shore plant. Feed ranged from 0.4 to 0.8 lb. SnO_2 per cyd. Average monthly throughput per dredge was 400,000 cyd. A typical side assembly is shown in Fig. 148.

Reuong Tin Dredging Co., Ltd. (*33 CEMR 10*), at Kuala Lumpur, Fed. Malay States, working in very clayey ground, sends the oversize of the primary screen to a second revolving washing screen with 5×4-in. slots, oversize to waste; undersize to 2 heavy-duty log washers, log product to waste; log overflow to a vibrating screen which rejects oversize, tailing being returned to the primary screen. Primary-screen undersize is jigged in the usual fashion.

Hydraulicking with hydraulic elevators is done when conditions are favorable. At GAPENG CONSOLIDATED, Malaya (*126 J 1016*), sluices 350 ft. long, sloping 1 in 50, lose about 7% of the cassiterite fed; about 7/8 of this is recovered by Chinese tributers.

Cocks Eldorado dredge. Fig. 149 (*29 CEMR 186*).

Location: Eldorado, Victoria, Australia.
Ore: Gravel containing clean, readily amalgamable gold and cassiterite.
Capacity: 10,000 tons per 24 hr.
Assays: Concentrate, 71% Sn.
Recovery: Sn, 95%; Au, 99%.



Legend for Fig. 149:

1. Revolving screen, 3/8-in. aperture.

2. 10 primary jigs.

3. 2 @ 4-cell secondary jigs. Analyses: hutch 1, 473 dwt. Au, 28.3% Sn; hutch 2, 1.9 dwt. Au, 2.1% Sn; hutch 3, 2.9 dwt. Au, 2.0% Sn; hutch 4, 0.2 dwt. Au, 0.3% Sn; tailing, 0.01 dwt. Au, trace Sn. Hutches 1 and 2, amounting to about 2 t.p.d. and representing 1/5,000 of the feed, are combined into a product assaying 5 to 10 oz. Au and 5 to 10% Sn. The gold is clean, amalgamates readily, and is mostly 65~100-m.; the cassiterite and ilmenite are about 28~100-m.; quartz and tourmaline are somewhat coarser; topaz, sapphire, corundum, and zircon are mostly 100~150-m.

3a. Hutches 3, 4.

4. To shore plant.

5. 1 @ 2-cell Harz jig, 36×15-in. with 30×28-m. screen, BB-shot bedding, 200 @ 3/16-in. s.p.m.; tailing comprises quartz, tourmaline, and some of the gems.

6. 3(diam.)×5-ft. amalgamating barrel, 15 r.p.m.; charge about 1 ton of concentrate in pulp containing 30% solids, with 20 to 30 oz. Hg; ground 2 hr.

7. Mercury trap.

8. 1 @ 2×6-ft. amalgamating plate, slope 2 in. per ft.

9. 1 @ No. 11D Wilfley table, 6×15-ft. deck, with riffles modified to handle large concentrate and small tailing tonnages; gem crystals are mostly flat and difficult to wash away from the generally rounded cassiterite. Tailing, 0.5% Sn.

10. 1 @ 30-in. (disk) Rapid magnetic separator, 2 @ 6-in. belts; capacity, 2 1/2 to 3 tons per 8 hr.; 3-kw. 110-volt motor-generator set used to energize. Tailing is re-run until <0.35% Sn.

FIG. 149. COCKS ELDORADO DREDGE.

Lode Ores

Primary tin ores almost invariably have cassiterite as the principal tin mineral, but it is a rare case in which cassiterite is the only heavy mineral present. Usually sulphides, principally iron, are present; tungsten in more or less important amounts is a frequent associate; arsenic minerals are not infrequent; and gold and silver in economic quantities occur in some ores. Since cassiterite is not, so far as present (1941) knowledge goes, economically floatable, but has a high specific gravity, concentration is effected by gravity means; and since, further, the value of tin per unit in concentrate is high, and increases markedly with increase in grade of concentrate, and the habit of cassiterite leans toward fine dissemination, the mill chase for pure tin mineral goes to great lengths. Tailing is dressed, scavenged, and rescavenged several times, and concentrate is cleaned, recleaned and re-recleaned. Furthermore, since the most efficient operation of gravity concentrating machines requires sizing or sorting as preparatory operations, and since each such preparatory operation and each gravity treatment adds considerable water, which must usually be removed before subsequent treatment, the screening, classification, and dewatering sections of the tin-mill flowsheets are often more extensive even than the concentration sections.

Gravity concentrate usually contains many heavy impurities. Magnetite is removed by low-intensity magnets, and iron-bearing tungsten minerals, garnet, and epidote by high-intensity magnets; sulphides may be reduced to a relatively low figure by flotation; an alternative treatment for pyrite is a magnetizing roast followed by magnetic separation, which may be supplemented by gravity concentration to remove nonmagnetic iron oxides rendered porous in the roasting; sulphuric acid leaching has also been practiced for removal of such iron. Final removal of sulphur and arsenic is effected by dead roasting. Volatilization of tin from tin-pyrite concentrate has been experimented with.

Treatment of a simple cassiterite-gangue ore is typified by Chinese (KOTCHIU) practice; the PATIÑO and COLQUIRI mills are treating sulphide-bearing ores low in silver; the POTOSI mill receives both sulphide and oxidized ores; the sulphide ore treated in the ORURO mill is high in silver; the SAN ANTONIO ore contains argentiferous oxidized lead minerals; the

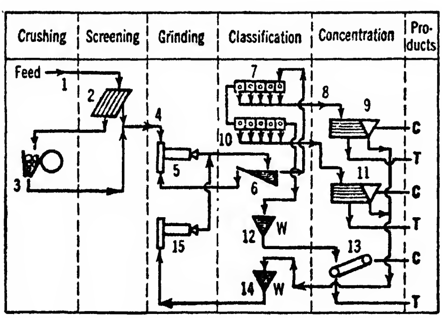
BEATRICE ore contains arsenic; the MAWCHI mill illustrates the making of a collective tin-tungsten concentrate, which is separated later by dry high-intensity magnetic treatment.

Recoveries (1939) at the Bolivian lode-ore mills are reported (*21 MMt 386*) as 80.79% on 3.66% ore at PATIÑO, 68% on 2.64% ore at OPLOCA, 68% on 2.38% ore at BOLIVIAN TIN & TUNGSTEN, and 68% on 2.88% ore at ARACA.

Chinese tin milling (after Draper, *12 MMt 178, 242*). The important deposits are in the Kotchiu district, in southern Yunnan, near the Burma, Siam, Indo-China borders. The principal ores are cassiterite, finely disseminated in a soft clayey mixture of limonite and porous hematite, which is probably an oxidized residue of a replacement deposit in limestone. Copper, as malachite, runs 1 to 2%. There are also small amounts of Pb, Zn, and As in oxidized form. Tin content averages above 5%. Most of the ore is milled by hand; the process starts by spreading the ore in a layer a few inches thick on a tamped clay floor, and pounding and crushing it with flails. The small amount resisting such disintegration is separated out and broken by foot stamps, or by Chilean mills with ±9-ft. granite wheels having 6×6-in. cast-iron tires wedged on, running on a stone or cast-iron race, 20 ft. in diameter, and driven by a water buffalo. Crushed material is concentrated on planillas (Sec. 11, Art. 32) about 5 × 6 ft. The first planilla, which yields a rough concentrate assaying 50 to 55% Sn is sloped about 20°, and worked with much water. Tailing is scavenged on flatter slopes and concentrate is cleaned and recleaned many times at successively steeper slopes and with progressively smaller amounts of water until at the final stage the slope is about 45° and the water a mere trickle. Grade of concentrate is customarily about 68.5% Sn. Recovery averages about 70% and ratio of concentration is 12 or 15 to 1. Cost of concentration (excluding crushing) is $1 to $2 per ton (1931). The one mechanized treatment plant in the district is diagrammed in Fig. 150.

Yunnan Kotchiu Tin Trading Co. Fig. 150 (*12 MMt 242*).

Location, Kotchiu, Yunnan, China.
Ore: Cassiterite in clayey limonite and hematite.
Capacity: 300 tons per 24 hr.



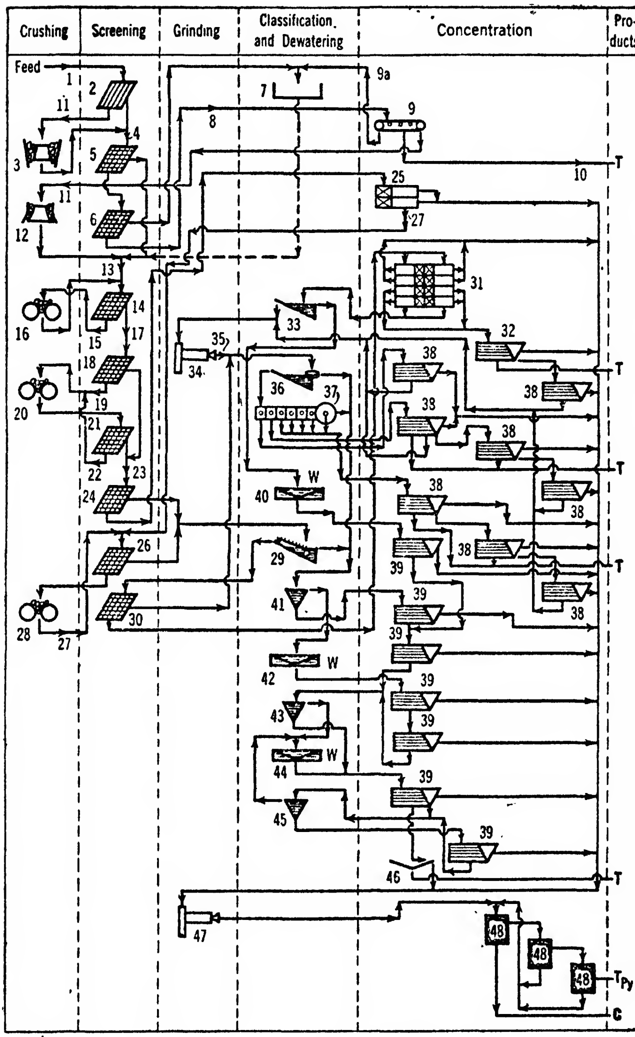
Legend for Fig. 150:

1. 100-ton masonry bin; hand tramming to top floor of mill.
2. 1 @ 6×10-ft. grizzly, 1 1/2-in. aperture.
3. 1 @ 12-in. jaw crusher, set 1-in.
4. 50-ton bin, reciprocating feeder.
5. 1 @ 5×8-ft. Marcy rod mill.
6. Dorr classifier.
7. Launder classifier, Deister cone-baffle sorting columns.
8. Separately.
9. 8 Wilfley tables.
10. Launder classifier.
11 20 Deister Plat-O, 6 Wilfley, 4 Ferraris tables.
12. 4 V-bottom thickening tanks.
13. 12 twin-belt vanners, 4 Ferraris tables.
14. Thickening cones.
15. 2 Krupp ball mills; 1 tube-pebble mill.

FIG. 150. YUNNAN KOTCHIU TIN TRADING CO.

Patiño M. and E. Consolidated, Inc. Fig. 151 (*138 J 299*).

Location: Catavi, Bolivia, S. A.
Ore: Cassiterite and pyrite in a siliceous gangue.
Capacity: 2,200 tons per 24 hr.
Assays: Mill feed (after sorting; see item (10) of flowsheet), 3.8% Sn; concentrates: gravity, 45.69% Sn; after flotation, 64.68% Sn, 0.20 Bi, 3.96 Fe, 0.05 Cu, 0.15 Pb, 0.17 Zn, 1.72 S, 0.09 As, 0.56 WO_3, 2.42 Al_2O_3, 5.8 SiO_2, 1.12 TiO_2, 0.09 P; tailings: sand, 0.43% Sn; slime, 0.90% Sn; combined sand and slime, 0.70% Sn; flotation froth, 0.85% Sn.
Recovery: Jigs, 18.5%; sand tables, 54.8%; slime tables, 7.8%; buddles, 0.6%; total, 81.6%. Of this total, flotation recovers 99.44%, making an over-all recovery of 81.2%.
Ratio of concentration: 20.6 : 1.
Power: 27 hp-hr. per ton milled.
Tailing disposal: Sand tailing dewatered in 4 large Esperanza drag classifiers which discharge onto a 16-in. conveyor discharging into a 500-ton loading bin for an aerial tram which, in turn, stacks it automatically along a dam line 1.2 mi. long. Slime tailing is thickened in 1 @ 120-ft. and 1 @ 75-ft. Dorr thickener and pumped by an 8-in. Wilfley pump behind the sand-tailing dam.
Costs (1935): Labor, $0.40; supplies, 0.50; power, 0.45; total, $1.35 (U. S.), excluding items preceding (14) on the flowsheet.



Legend for Fig. 151:

1. 2-ton cars from mine; 1 @ 650-ton concrete bin; chute feeders; 30-in. belt conveyor.

2. 2 bar grizzlies, 3-in. spacing.

3. 2 @ 13-in. McCully gyratories.

4. 1 @ 24-in. conveyor.

5. 2 @ 4×8-ft. trommels, 1 1/2×3-in. slotted plate.

6. 2 Leahy vibrating screens with washing sprays.

7. Settling tanks. Contents dried and sent to mill at irregular intervals.

8. 1 @ 24-in. conveyor; 1 @ 900-ton bin; 4 @ 36-in. apron feeders.

9. 2 @ 30-in. inclined picking belts in parallel, 30 f.p.m. Ore is washed as it feeds onto belt. Space provided for 104 pickers (women).

9a. Washings.

10. 12 to 20% of r.o.m., assaying 0.5 to 0.9% Sn; 16-in. conveyor with weightometer; movable spreader-conveyor on waste dump.

11. Magnetic protection.

12. 2 @ No. 6 Traylor reduction gyratories, set 1 1/2-in.

13. 1 @ 20-in. conveyor; 1 @ 18-in. shuttle conveyor; 1 @ 3,200-ton concrete bin; 30-ton railroad cars 2 mi.; track scales both ends of haul; 1 @ 2,500-ton mill bin; 8 feeders; 2 @ 30-in. inclined conveyors.

14. 4 @ 4×10-ft. trommels, 16-mm. screen.

15. 1 @ 24-in. inclined conveyor.

37. 8 @ 7-spigot Fahrenwald classifiers.
38. 45 Deister Plat-O tables, used for >80-m. sands.
39. 55 Deister-Overstrom tables, used for <80-m. feeds.
40. 2 @ 20-ft. thickeners.
41. 11 @ 8-ft. Fahrenwald cones.
42. 2 @ 20-ft. and 2 @ 30-ft. thickeners.
43. 21 @ 6-ft. Fahrenwald cones.
44. 2 @ 30-ft. thickeners.
45. 3 as (41).
46. 13 center-discharge buddles.
47. 1 @ 5×10-ft. rod mill.
48. 8 MacIntosh flotation cells.

Summary. Crushing to 3-mm. in 5 stages; rejecting tailing at 3~1 1/2-in. by hand picking; treating sized products on jigs down to 1-mm. and finer sizes, extensively classified, on tables; all gravity concentrate cleaned by flotation to remove sulphides, principally pyrite.

This flowsheet is typical of the treatment of Bolivian ores in which the values are substantially all tin.

Compañía de Minas de Colquiri. Fig. 152 (*Q; 2 #4 FMQ 12*).
Location: Colquiri, Bolivia, S. A.
Ore: Cassiterite and sulphides (principally pyrite) in quartz veins in slate.
Capacity: 700 tons per 24 hr.
Assays: Feed: Sn, 3.00%; soluble Sn, 0.16; Pb, 0.93; Zn, 1.90; Cu, 0.52; Fe, 20.6, S, 11.6; Ag, 0.12 oz., SiO_2, 26; Al_2O_3, 22.2; Sb, 0.5; concentrates: High-grade, 64% Sn; low-grade, 45% Sn. (See also Table 111.) Tailing, see Table 111.

Recovery: 78%.
Ratio of concentration: 28.6 : 1.
Running time: 90% of possible; lost time due to repairs and holidays.
Power: Hydroelectric; comes 25 mi. at 22,000 volts; motors, 440-volt, 50-cycle; CONSUMPTION, 34.6 hp. per ton milled.
Labor: Native labor with American shift bosses; tons per man-shift: operating, 1.6; repairs, 11.8.

Water: Comes 6,900 ft. from a creek by 2 @ 6 1/2×9-in. Aldrich Triplex pumps in series, 480 r.p.m. against a static head of 594 ft. (total head, 690 ft.), 200-hp. for pumping; water CONSUMPTION, 20 tons per ton milled, of which upward of 90% is recirculated.

Mill building: Wood frame with corrugated-iron sheathing; sloping site; floors concrete, slope 1/2 in. per ft. in wet section. Unheated.

Machinery handling: Chain hoists on rails in crushing and flotation sections, by hand in table section.

Tailing disposal: Wilfley pumps elevated to main tailing launder. Pyrite elevated in 3 stages by 2-in. Wilfley pumps.

Distances: Mine to mill, 0.6 mi. by electric tram; concentrate (1% moisture) 40 mi. by highway to railroad, thence by train and boat to Liverpool, England, or to U. S.

60. 1 @ 50-ft. thickener, 9 min. per rev., 7 1/2-hp. motor.

61. Denver unit cell.

Summary. Three-stage crushing; 4-stage step-grinding of middling; coarse roughing on jigs and tables to discard rock tailing; flotation to scalp sulphide out of reground middling; table concentration of flotation tailing (tin rougher concentrate) to make finished tin concentrate, rock tailing, and a middling which is reground, rescalped by flotation, and reconcentrated by tabling.

A sink-float suspension run on a 25-ton experimental unit treating >2-mm. material gave promising results (*22 MMt 71*).

Cía. Minera Unificada del Cerro de Potosí. Fig. 153 (*Q; 2 #4 FMQ 11*).

Location: Potosi, Bolivia, S. A.

Ore: Cassiterite (2.5%), stannite (0.7%), chalcopyrite (0.25% Cu), and pyrite (35%) with quartz and barite in slate and porphyry.

[General data continued on p. 234.]

75. 1 Deister-Overstrom table, 311 s.p.m.

76. As (75).

77. High-grade.

78. Alternative or part.

79. 1 @ 12-ft. thickener, 3 min. per rev.

Capacity: 750 metric tons sulphide ore as above and 750 tons oxidized ore in a parallel sand-table section per 24 hr. All oxide slimes sent directly to the sulphide plant and all oxide-plant rough concentrate joined with rough sulphide-plant concentrate for regrinding (see Fig. 153, item 70).

Assays: Feed, 2% Sn; concentrate (high-grade): 60 to 65% Sn; Ag, 2 oz.; Pb, 0.02%; Zn, 0.18; Cu, 0.20; As, 0.25; Sb, 0.10; Bi, 0.02; S, 1.65; Fe, 2.5; SiO_2, 8.0%. Low-grade concentrate: Sn, 30%; Ag, 1.50 oz.; Pb, 0.12%; Zn, 0.25; Cu, 0.35; As, 0.88; Sb, 0.15; Bi, 0.04; S, 3.71; Fe, 6.40; SiO_2, 36%. Tailing: 0.7 to 0.8% Sn aver.

Recovery: 50 to 60%.

Ratio of concentration: 50 : 1.

Running time: 85%; principal losses: repairs, 5; power, 3; fiestas, 2; water shortage, 5%.

Power: Hydroelectric; Diesel stand-by. Comes in at 44,000 volts (Al line); motors, 440-volt, 50-cycle. CONSUMPTION, 58.5 hp. per ton milled, average.

Labor: Bolivian; 3.84 tons per man-shift operating; repairs, 25 tons.

Water. 9 mi. by gravity pipe line from a reservoir. CONSUMPTION: 4 tons new water per ton of ore milled; 10 tons total; normal re-use, 60%; 90% in dry season.

Mill building: Timber and steel frame, corrugated-iron walls and roof, CEL-O-GLASS windows. Sloping site. Cement and sandstone-paved floors. Heated with salamanders.

Machinery handling: Hand crawls over crushers and flotation machines.

Tailing disposal: Jig tailing to river (stacked by aerial tram in dry season); pyrite float pumped to storage dam; table tailing by gravity to storage dam.

Distances: Mine to mill about 1.6 mi. by aerial tram (Bleichert double-rope, capacity 60 t.p.h.). Concentrate (<1.0% H_2O) hauled about 0.6 mi. to railroad, thence to coast, boat to England or U. S. A.

Summary. Two-stage crushing through 3.6-mm. Tailing scalped out of >1-mm. size in jigs; jig middling together with <1-mm. primary stream ground through 0.5-mm. Pyrite scalped out by flotation and quartzitic gangue removed by elaborate step classification and tabling, with finest slime treated on a round table. Round-table concentrate desulphidized by flotation. All gravity concentrate combined, reground, floated to remove pyrite, and tabled to produce high- and low-grade concentrate.

Cía. Minera de Oruro. Fig. 154 (*Q*).

Location: Machacamarca, Bolivia, S. A.

Ore: Cassiterite with pyrite, galena, franckeite, and stephanite, in slate.

Capacity: 250 tons per 24 hr.

Assays: Feed: 4% Sn, 20 oz. Ag per ton; concentrate: silver precipitate, 32% Ag; tin, 46% Sn.

Recovery: Ag, 77%; Sn, 56%.

Ratio of concentration: Varies with ore, which is highly variable.

Water comes 2 mi. from river by ditch. CONSUMPTION, 30 tons per ton of ore; about 20% re-used during dry period.

Power: Hydroelectric, purchased. Comes 3 mi. at 13,000 volts. Motors, 500-volt, 50-cycle. CONSUMPTION, 62 hp-hr. per ton of ore.

Labor: Native Bolivian except one foreign foreman; 0.5 tons per man-shift.

Running time: 96%.

Mill building: Slightly sloping site. Timber frame with galvanized-iron covering. Concrete floors, slope 3/16-in. per ft. in flotation section, which is insufficient. Unheated. Hand cranes throughout.

Transportation: Mine to mill, 23 mi. in 25-ton railroad cars. Concentrate all shipped to United States. Silver precipitate shipped with 0.2% moisture, tin concentrate with 2% moisture.

Tailing disposal: Pumped to dam, from which water is recovered during dry season.

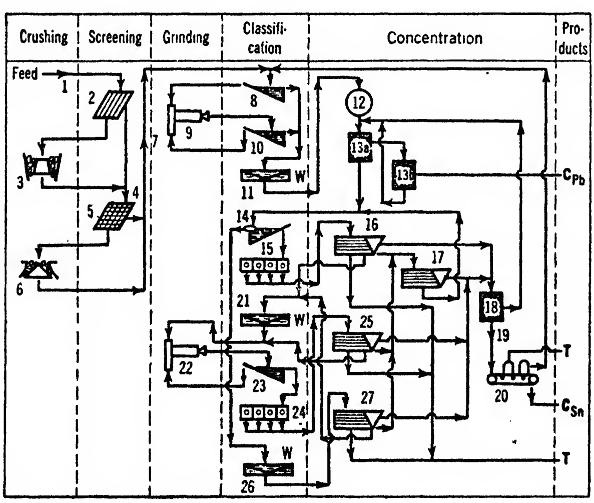
Summary. Three-stage crushing to 2- or 3-mm. Recovery treatment is essentially repetitive gravity concentration of cassiterite from siliceous gangue after silver and copper have been leached out or arsenic and iron have been floated off, according to the character of the feed.

American Smelting & Refining Co., San Antonio mine. Fig. 155 (*137 J 126*)

Location: Chihuahua, Mexico.
Ore: Argentiferous cerussite and plumbojarosite with cassiterite in a ferruginous lime-quartz gangue.
Capacity: 200 tons per 24 hr.
Assays: Feed: 12% Pb, 300 gm. Ag per ton, 0.5% Sn, 15 to 20% Fe, 10 to 14% CaO, and 30% SiO_2
Recovery: Pb, 85%; Ag, 85%; Sn, 35%.
Ratio of concentration: Pb, 5.7 : 1; Sn, 200 : 1.



Legend for Fig. 155:

1. 20 mi. by rail from mine to mill; bins; conveyor.

2. Grizzly.

3. 1 @ No. 5 A-C gyratory crusher, set 2 1/2- to 3-in.

25. 10 tables apportioned as (16).
26. Thickener, spigot 20% solids.
27. 13 Deister Plat-O slimers.

Summary. Two-stage crushing to <1/2-in.; one-stage primary rod-mill grind to flotation-feed size; primary rougher-cleaner flotation to remove the bulk of the lead and silver; sand-slime separation of flotation tailing and separate tabling of the products after hydraulic classification of sands; all primary-table middling reground and retabled, after hydraulic classification, in a separate circuit; all primary-table high-grade concentrate refloated for a lead middling and the flotation tailing dried and reconcentrated magnetically to remove iron; all low-grade table concentrate retabled, making rich concentrate for the flotation-magnetic circuit and cleaner tailing for return to the middling-regrind circuit.

Beatrice mine. Fig. 156 (*46 MM 20; 126 J 1016*).

Location: Selibin, Fed. Malay States.
Ore: Cassiterite with arsenopyrite and chalcopyrite in tremolite and fluorite.
Assays: Feed: 12 to 20% cassiterite.

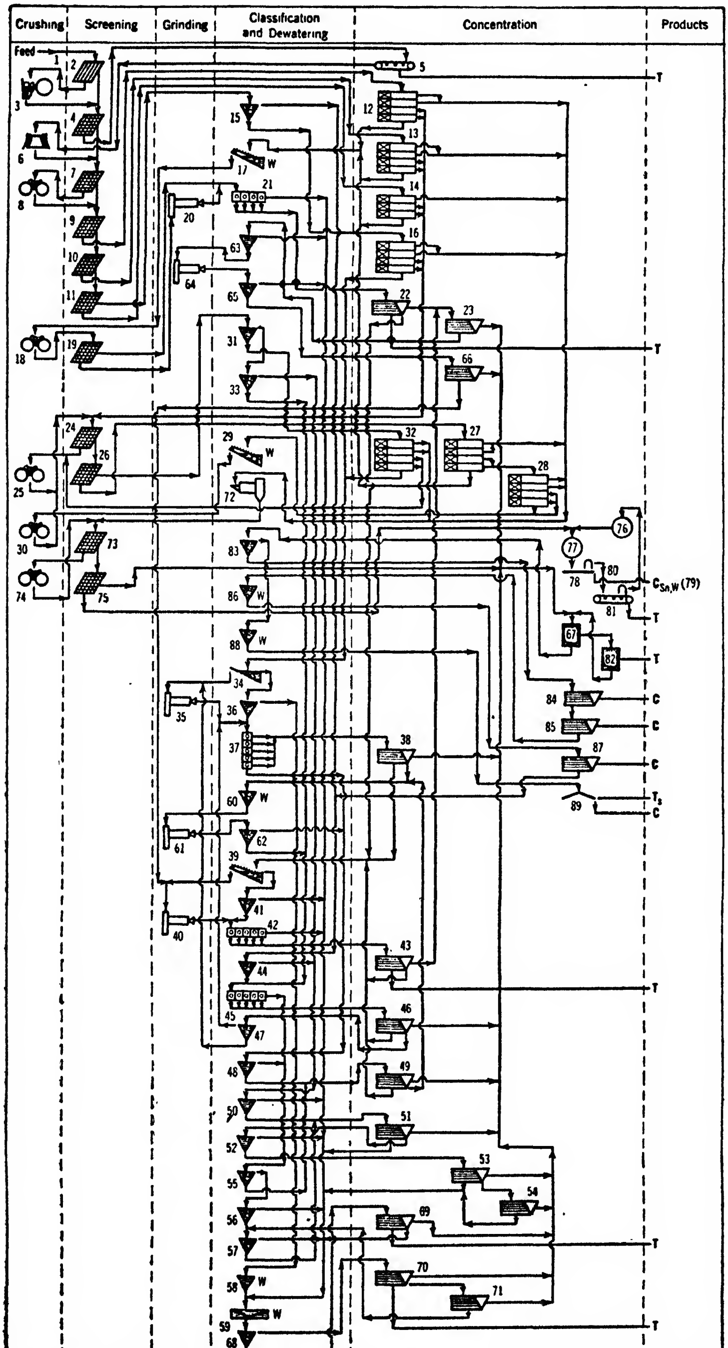

FIG. 157. MAWCHI MINES.

Legend for Fig. 157 on page 239.

Summary. Closely graded crushing, screening, and jigging, beginning at 8-mm.; primary jig middlings recrushed and separately rejigged. Fines, including recrushed jig tailings, to classifiers and tables. Coarse concentrate (8% As + S) freed from sulphides by Murex process (Sec. 12, Art. 16); fine concentrate (<1-mm.) by batch flotation. Chief aim at this mill is to make maximum possible recovery in coarse sizes, suitable for extraction of sulphides by Murex process; also to facilitate final magnetic separation of wolframite from cassiterite, not feasible with <180-m. material.

Consolidated M. & S. Co. of Canada, tin mill. Fig. 158 (*44 CIMM 611; Tref 1/42*).

Location: Sullivan concentrator, Chapman Camp, B. C.
Ore: Zinc-plant tailing (Fig. 116). Tin principally cassiterite, @ 7% >200-m., 15% <1,500-m.; gangue about 65% pyrrhotite, 5% pyrite-arsenopyrite, minor amounts of galena and marmatite.
Capacity: 5,000 t.p.d.
Assays: Feed, 0.2% cassiterite (1 to 1.5 lb. Sn per ton); concentrate, 83% cassiterite.
Recovery: 45%.
Ratio of concentration: 2,000 : 1.

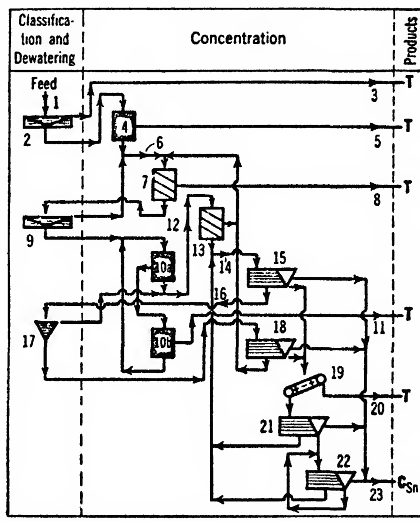

FIG. 158. CONSOLIDATED M. & S. Co., tin plant.

Summary. Sulphide roughed out by flotation and gangue by tilting frames, reducing tonnage for final cleaning on shaking tables to about 1/450th. One-stage cleaning on tables with two cleanings of primary-table middling.

45. TITANIUM

Uses. Pure metal has no special applications; its alloys serve both ferrous and nonferrous metallurgy. "Konel," Fe-Co-Ni-Ti, has the same expansion coefficient as glass, and replaces platinum in incandescent lamps. The artificial oxide is a brilliant white pigment, with notable hiding power and atmospheric resistance. Uses as pigment and/or filler are in paints, rubber, paper, asbestos shingles and siding, cosmetics, toilet soap, rayon, asphalt tile, linoleum, plastics, leather finishes, textiles, enamels, wall board, and glue. The natural oxide develops a honey-yellow glaze on ceramics, and is widely employed as a fluxing coat on electric welding rods. Titanium trichloride is a bleaching agent, other salts are employed for dyeing, and the tetrachloride is the compound used for skywriting and smoke screens.

Occurrence. Commercial supply of titanium comes from only two minerals: rutile, the dioxide (60% Ti), and ilmenite, an impure ferrous titanate (FeO,TiO_2) in which both metals are often partly displaced by others. The enormous known deposits of titaniferous magnetite are just beginning to be worked for titanium. Both rutile and ilmenite, frequently together, are found both in massive rock formations and in beach sands. The more important hard-rock localities are at Roseland, Va., where a pegmatite carries about 4% each of rutile and ilmenite; Piney River, Va., where ilmenite occurs with apatite·

Kragero, Norway; and Baie St. Paul, Quebec. The most productive beach deposits are at Manavalakurichi and Quilon, in southwestern India; at Guarapary, Boa Vista, and Prado, Brazil; and at Byron Bay, New South Wales. Portugal, Senegal, and the Cameroons produce beach concentrates (formerly also Florida and California), and ilmenite is now being recovered from the tailings of alluvial tin workings in Malaya, Billiton, and the Congo. Average TiO_2 contents of concentrates shipped from the several localities, in per cent., are: Roseland, Va., ilmenite, 54; rutile, 95 to 96; Piney River, Va. (after an acid leach), 48 to 50; Trovancore (India), 50 to 53; Brazil, 52.7; Norway, 42 to 43; and New South Wales (rutile-ilmenite mixture), 75.9. Some Indian shipments in 1939 were reported to assay: TiO_2, 60.35; Fe, 22.69; SiO_2, 0.41; S, 0.01; P, 0.03%. Bauxite is a potential source; tailing of the St. Louis plant of the Aluminum Co. at East St. Louis is reported (*30 CIMM 802*) to contain 75,000 lb. TiO_2 per day.

Production. World production is given in Table 113. Cameroon exported 120 met. tons of rutile in 1938. Data on domestic production are not available; Virginia has been the chief contributor, but some rutile-brookite concentrate has come from Hot Springs County, Ark. Demand for rutile (used mainly for welding-rod coatings and the nonferrous alloys and chemicals) is sufficiently supplied from domestic sources; that for ilmenite (mainly for pigment manufacture) requires heavy imports (over 200,000 tons annually, in recent years) coming mainly from India. But see Fig. 159.

Prices. In 1938–1939, ilmenite (50 to 60% TiO_2) was quoted at $10 to $12 per long ton, f.o.b. Atlantic ports. Rutile (94 per cent. minimum purity) at 10¢ per lb.; 88 to 90%, at $60 per long ton, c.i.f. New York. Ilmenite imports in 1938 were valued at $5.05 per long ton.

Treatment. Early (1922) practice at Roseland, Va., included crushing by stamps, classification, and Wilfley concentration; tailing discarded, middling returned to stamps, and concentrate (dried) to Wetherill magnetic separators of ilmenite from rutile. On the Florida coast, near St. Augustine, a mill operated for a short time (about 1927) on sands containing about 20% of mixed valuable minerals; concentrate from 18 Deister-Overstrom tables contained 55% ilmenite, 20% zircon, 6% rutile, 2% monazite, and 17% quartz and silicates. Magnetic separators made clean ilmenite, and middlings which were subdivided into rutile, zircon, and monazite by electrostatic separators and wet tables (*IC 6365*). For results at Byron Bay, N. S. W., where chief product is zircon, see Art. 49. For manufacture of titanium pigment from ilmenite, see *42 CME 595*. At BURDICK MINERAL CORP. (*IC 6365*) beach sands are passed over 30-m. Leahy screens; oversize wasted; undersize containing 60% mixed ilmenite and magnetite is tabled, and the concentrate dried and separated by low-intensity magnets to yield relatively clean magnetite and ilmenite.

28. Titanium middling.

29. 4 @ 10-ft. Allen cones.

30. 4 Hydroseal pumps.

FIG. 159. NATIONAL LEAD CO., Titanium Division.

Summary. Three-stage crushing from steam-shovel size to 3/4-in. and one-stage closed-circuit (screen) rod milling to 16-m. Concentration on the primary stream only; magnetic separation for magnetite and tabling for ilmenite, with circulation of gravity middling through the grinding circuit.

46. TUNGSTEN

Uses. More than 99% of all tungsten mined goes into the manufacture of ferroalloys and tungsten steels. Tungsten is an essential element of high-speed tool steels, which are indispensable in present-day manufacturing. The carbide is extremely hard, and tough enough so that it is invaluable to tip cutting tools, face dies, etc. Other uses for the metal are for magnet steel, alloys with aluminum, copper, zinc, nickel, cobalt, molybdenum, chromium, manganese, vanadium, titanium, and other metals, radio and lamp filaments, electrical apparatus, X-ray tubes, needles for sound reproduction, and as a catalyzer in production of ammonia from atmospheric nitrogen. Tungsten salts are used for fire-proofing cloth, as mordants in dyeing, and for coloring glass and porcelain.

Ores. The economic minerals are scheelite, hübnerite, ferberite, and wolframite. Deposits are usually placers or fissure veins; less commonly in pegmatites and contact-metamorphic zones. The usual gangue minerals are quartz, fluorite, cassiterite, tourmaline, mica, etc., occasionally sulphides. The country rock is commonly granite, less frequently quartzite, limestone, and metamorphic rocks.

Production. World production of tungsten concentrate (60% WO_3) is given in Table 114.

Table 114. World production of tungsten ores (metric tons of 60% WO_3 concentrates) (*MI*)

Selling. See Art. 50. PRICES of tungsten in concentrates (60% WO_3), per short-ton unit of WO_3: 1929, $13.13; 1932, $9.20; 1937, $19.50; 1938, $17.31; 1942, $24.00.

Treatment. Tungsten concentrate for steel making should contain upward of 60% WO_3 and less than 0.5% each of Sn, Cu, As, P, and S. This requirement translates into 75 to 80% tungsten mineral in concentrate and substantially complete elimination of cassiterite, sulphides and the like, and apatite. Much lower grades are acceptable for chemical manufacture (material with as little as 3% WO_3 can be treated), but prices per unit of tungstic acid fall with the added tolerance, and freight and penalties are normally prohibitive if the WO_3 content is less than 10%.

The specific gravities of the tungsten minerals, ranging from 5.4 to 6.1 for scheelite to 7.5 for ferberite, make gravity separation from rocky gangues highly efficient in the sand sizes. But when the tungsten mineral is finely disseminated, losses in gravity treatment are high because the tungsten minerals are brittle and friable and slime badly in fine crushing and grinding. Better recoveries, but with lower grades of concentrate, can be made by flotation, using either anionic or cationic collectors. The iron-bearing tungstates (ferberite and wolframite), which are the ones likely to be present with Sn, Cu, and As minerals, are sufficiently permeable to permit magnetic separation.

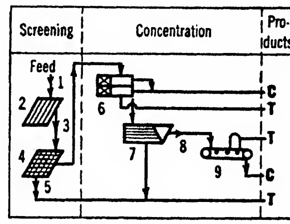
The typical basic flowsheet, where tungsten is the principal value, comprises graded crushing, screening, and classification to produce a number of closely graded products, and concentration of these on jigs and tables. Middling is recrushed or lightly ground and returned to the primary stream. Shaking tables are preferable to buddles or strakes for slimes because of the higher grade of concentrate that can be made on them. Gravity tailing may be scavenged by flotation. Methods of grading up gravity concentrate depend upon the impurities present. Sulphides are usually floated with sulphydric collectors; residual S and As are removed by roasting; iron may be removed from roasted concentrate magnetically or by leaching. Tin is separable from wolframite either before or after roasting by removal of the wolframite on high-intensity magnets, but separation of tin from scheelite cannot be made by this means. Prices of concentrate may be sufficiently high in the United States and Canada to permit treatment of ores containing as little as 0.1% WO_3.

Placer tungsten represents residuals from relatively deep weathering *in situ* with little working over by streams. Placers have been the most important sources of tungsten in the past, especially those at Kiang Si and Kwantung in China. Treatment has been largely hand operation, with picking of coarse lump, hand jigging of gravel, and repeated planilla reconcentration of fines. Fig. 160 shows the flowsheet of a modern placer-ore mill at ATOLIA.

Atolia Mining Co.; placer mill, Fig. 160; lode-ore mill, Fig. 163 (*IC 6532*).

Location: Atolia, near Mohave, Calif.
Ore: PLACER: Scheelite in coarse detritus from disintegrated tungsten-bearing quartz monzonite. LODE: Relatively coarse scheelite crystals with some apatite, pyrite, and magnetite in quartz veins in quartz monzonite.
Capacity: PLACER MILL, 800 tons per 24 hr.; LODE-ORE MILL, 150 tons per 24 hr.
Assays: Placer concentrate: 62% WO_3, 0.010% P, S negligible. Lode concentrate: 66.6% WO_3, 0.16% S, 0.034% P, 0.007% As, trace Cu. Tailing about 1 lb. scheelite per ton.
Recovery: Placer ore: 70%.

Ratio of concentration: Placer ore, 1,369 : 1; lode ore, 400 : 1.
Water: Pumped 7 mi. from a well against a head of 650 ft.; CONSUMPTION, placer mill, 1.25 tons per ton milled; lode mill, 1.25 tons per ton milled.
Power: Purchased at about 2¢ per kw-hr. Comes 4 mi. at 2,200 volts. Motors 440- and 220-volt. CONSUMPTION, milling only: placer mill, 3.1 kw-hr. per ton milled; lode mill, 9.3 kw-hr. per ton.
Labor: Placer mill: 28.4 tons per man-shift for power-shovel mining, trucking, and milling; lode mill, 13.6 tons per man-shift for milling only.
Mill building: Placer mill: Level site. Total floor area, 1,600 sq. ft. = 2 sq. ft. per 24-hr. ton.
Distances: Placer mine to mill, 1,000 ft.
Tailing disposal: Deslimed and dewatered by a drag belt; sands stacked by conveyor; slimes pumped to settling ponds, and clear water reclaimed.
Costs: Placer mill (1930), $0.27 per ton milled; lode mill (1929), $0.84 per ton milled.



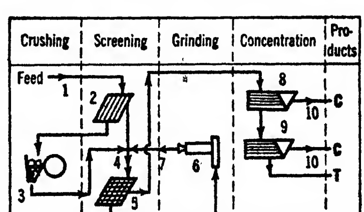
Legend for Fig. 160:

1. 1 @ 1-ton shovel; 1 @ 7 3/4- and 1 @ 5 1/2-ton truck.
2. 1 @ 6-in. grizzly; oversize sledged through.
3. Bin; belt conveyor.
4. Swing-hammer type screen disintegrator. Screen is 4×8-ft. cylinder, tire-mounted and driven, with 5/8-in. steel-plate shell perforated with 2-in. round holes. Hammers are 3×3×6-in. manganese steel chain-mounted on a 3 7/16-in. shaft which makes 50 r.p.m. counter to the screen revolution.
5. 1 @ 400-ton bin; belt conveyor; bucket elevator; tripper belt; 1 @ 250-ton bin; belt feeders.
6. 4 @ 25×34-in. 2-compartment Harz-type jigs, 0.03-in. screens, 10-in. bed thickness, 150 @ 5/8-in. s.p.m. Bed concentrate hand-skimmed every one or two shifts, comprises 85% of total concentrate and assays 60% WO_3 and 0.010% P; hutch product is about 25% of jig feed.
7. 1 Overstrom table (1 in reserve); middling recirculated on table; concentrate assay, 73% WO_3.
8. Wood-fired drying oven.
9. 1 @ 4-pole Wetherill magnetic separator; magnets wound for 30,000 and 60,000 ampere-turns; 1.5-amp. current on first magnet and 6-amp. current on second at 120 volts.

FIG. 160. ATOLIA MINING CO., placer mill.

Lode tungsten ores are usually more or less complex; the simple ones normally contain small amounts of pyrite and apatite in addition to the normal siliceous gangue; the complex ores, which are probably the more common, contain additionally heavy-metal sulphides and arsenic-antimony-bismuth compounds, frequently also cassiterite, which may be present in sufficient quantity to constitute the primary value. The ROUND VALLEY, WOLF TONGUE, ATOLIA lode-ore, and SILVER DYKE mills illustrate typical treatments of simple ores; the NEVADA-MASSACHUSETTS and IMA plants treat complex feeds. The MAWCHI mill, Fig. 157, is essentially a tin-tungsten operation. The BOLIVIAN ores constitute a variety of complex types.

Round Valley Tungsten Co. Fig. 161 (*6852 IC 25*).
Location: Bishop, Calif.
Ore: Coarse scheelite with garnet, epidote, and quartz.
Capacity: 120 tons per 24 hr.
Assays: Feed, 0.5% WO_3.
Power: 12.7 hp-hr. per ton milled.
Labor: 13.6 tons milled per man-shift.
Costs (1931): Crushing, $0.082 per ton milled; grinding, 0.245; tabling, 0.107; drying and sacking, 0.203; miscellaneous, 0.220; total, $0.857.



Legend for Fig. 161:

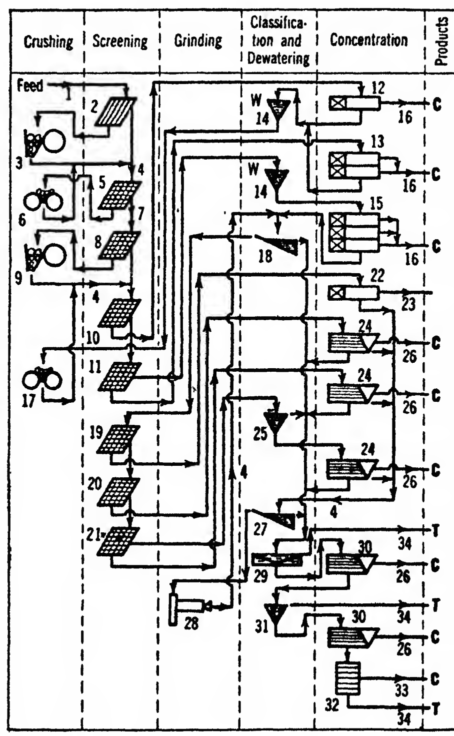
1. Bin.
2. Bar grizzly, 40° slope, 1-in. spacing.
3. 1 @ 10×16-in. Blake-type jaw crusher, 1-in. open set.
4. Belt conveyor; 225-ton bin with rack-and-pinion gate and 24-in. apron feeder.
5. Vibrating screen, 12-m. aperture; undersize contains about 14% <150-m.
6. 1 @ 4×5-ft. grate-type ball mill, 3/16-in. grate openings, ball load 3 1/2 tons 5-in. chrome-steel (consumption, 0.9 lb. per ton); feed pulp maintained at 6 of water to 1 of ore, and a large circulating load built up to minimize sliming.
7. Belt-bucket elevator.
8. 1 @ 5×18-ft. Overstrom table; makes about 90% of total recovery.
9. 2 as (8).
10. Drained, dried, and sacked by hand.

FIG. 161. ROUND VALLEY TUNGSTEN CO.

Summary. One stage of crushing and one stage of wet grinding in closed circuit with a 12-m. screen; tabling in two stages without cleaning or recirculation.

Wolf Tongue Mining Co. Fig. 162 (W. O. Vanderburg, *IC 6685*).

Location: Nederland, Colo.
Ore: Ferberite in quartz. Ferberite is heavy (sp. gr. 7.5) but slimes badly.
Capacity: About 1 t.p.h. on feeds containing about 4% WO_3 to 1/2 t.p.h. on 10% feeds.
Assays: Feed, about 5.5% WO_3; rich concentrate, 55% WO_3; poor concentrate 30 to 32% WO_3; tailing, about 1% WO_3.
Recovery: 85 to 87%. About 70% in rich concentrate. About 73% made on jigs.
Ratio of concentration: 9.7 : 1.
Water: Consumption, 6 tons per ton ore, net.
Power: Hp-hr. per ton of ore: crushing, 11.5; grinding, 7.2; conveying and screening, 5.8; jigging, 3.6; tabling, 7.6; total, 35.7.
Labor: 1.85 tons per man-shift.
Costs (1931): Crushing and grinding, $0.428; screening and conveying, 0.630; jigging, 0.803; tabling, 0.519.



Legend for Fig. 162:

1. By auto truck over platform scales to bins.
2. Inclined bar grizzly, 3/4-in. spaces.
3. 7×10-in. Blake crusher, 3/4-in. open setting.
4. Belt-bucket elevator.
5. 3×6 1/2-ft. trommel, 1/2-in. sq. aperture; slope, 2 i.p.f., 15 r.p.m.
6. 36×16-in. rolls.
7. Vezin sampler, storage bins, belt conveyor, mill-feed bin, pan feeder.
8. Trommel, 1/4-in. aperture.
9. No. 3 Universal jaw crusher, set about 1/4 in.
10. Trommel, 1/4-in. aperture.
11. Trommel, 1/8-in. aperture.
12. 1 @ 16 1/2×30-in. 1-compartment Harz bull jig, 3/8-in. screen, 5 1/2-in. bed, 250 @ 3/4-in. s.p.m.
13. 1 @ 16 1/2×30-in. 2-compartment Harz jig, 6-m. screen, 4 1/2-in. bed, 250 @ 1/2-in. s.p.m.
14. Dewatering box.
15. 1 @ 16 1/2×30-in. 3-compartment Harz jig, 10-m. screen, 4 1/2-in. bed, 250 @ 1/2-in. s.p.m.
16. Two grades of concentrate made, *viz.:* 50 to 60% WO_3 and 30 to 40% WO_3. Concentrate discharge is by hand skimming, with a general clean-up at the end of each shift.
17. 14 × 27-in. rolls.
18. 1 @ 3×12-ft. Akins classifier.
19. 1 @ 20-m. screen.
20. 1 @ 40-m. screen.
21. 1 @ 80-m. screen.
22. 1 @ 6×14-in. Richards jig, 6-m. cloth, 5 /2-in. bed, making hutch conc. only.
23. 50 to 60% WO_3.
24. 1 Wilfley table.
25. Deslimer.
26. Two concentrates, 50 to 70 and 30 to 40% WO_3.
27. 1 Akins classifier.
28. 1 small Marcy ball mill, 2,000 lb. 1 to 4-in. balls, 36 r.p.m.
29. 1 @ 20×8-ft. thickener. Lime added to accelerate thickening.
30. 3 Deister-Overstrom slime tables.
31. Cone.
32. 3 @ 4×18-ft. canvas tables. Slope adjustable from 1/2 to 2 i.p.f. according to pulp density. Primarily pilots.
33. Impounded for future treatment.
34. Composite about 1% WO_3.

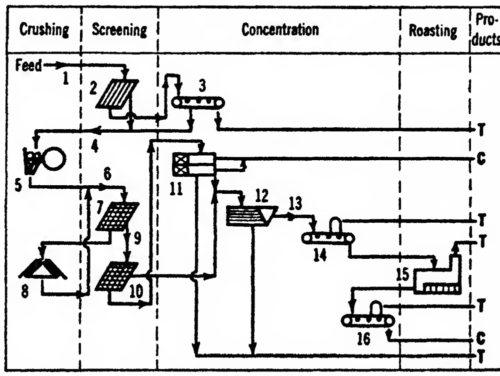
FIG. 162. WOLF TONGUE MINING CO.

Summary. Crushing from 6-in. to about 3/8-in. in 4 stages, with removal of undersize at each stage and the final stage closed on a screen and bull jig. Sizing to 8 grades. Separate

concentration of sized grades on jigs and tables. Middling reground, admixed with original slimes, and reconcentrated in two table stages followed by canvas tables.

Flotation tests indicated that a concentrate of 50% WO_3 grade could be made on crude ore with a recovery of 77% but that mill slime when raised to the same grade would lose about 50% of the values. Reagents used were sodium oleate and oleic acid, pine oil and NaOH in the rougher, sodium silicate in the first cleaner, and H_2SO_4 in subsequent cleanings.

Atolia lode mill. Fig. 163 (see p. 244).



Legend for Fig. 163:

1. Shaft bin.
2. 2 1/2-ft. diam. revolving-disk grizzly, 3-in. spacing.
3. Sorting belt.
4. Bin.
5. 1 @ 10×16-in. Blake-type jaw crusher, 2-in. open setting.
6. Conveyor; elevator.
7. Vibrating screen, 1/8-in. aperture.
8. 1 @ 3-ft. cone crusher.
9. Conveyor; bin; reciprocating feeder, bucket elevator; operating time of crushing plant, 16 hr. per day.
10. 1 @ 2×5-ft. stationary screen, 0.0425-in. aperture.
11. 1 @ 2-compartment fixed-sieve jig, 17 1/2×27-in. @ 14-mesh screens; products are cup concentrate, tailing, and a hutch middling. Concentrate assays 65% WO_3, 0.02% S, 0.025% P.
12. 2 Overstrom tables; middling recirculated on tables by pump. About 90% of total scheelite recovery is made here. Concentrate assays 40% WO_3, 8% S (in pyrite), and 0.15% P (in apatite); there is also some magnetite.
13. Drying.
14. Wetherill magnetic separator to remove magnetite.
15. 1 @ 3 (diam.)×6-ft. 8-hearth Herreshaff roasting furnace, fired and fed to make pyrite magnetic; apatite decrepitates and about 75% of it passes off as furnace dust.
16. Same machine as (14). Concentrate assays 67% WO_3, 0.5% S, 0.08% P.

FIG. 163. ATOLIA MINING CO., lode-ore mill.

Summary. Two-stage crushing to 1/8-in. Jigging 1/8-in.~14-m. and tabling <14-m. Table concentrate cleaned on magnetic separator to remove magnetite, then roasted and retreated on the magnet to remove pyrite.

Silver Dyke Mining Co. (W. O. Vanderburg, *IC 6604*).

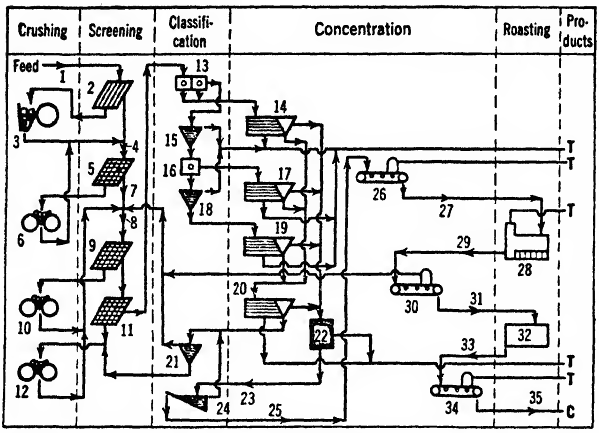
Location: Mineral County, Nev.
Ore: Scheelite, pyrite (coarsely crystalline), alabandite, quartz, monzonite.
Assays: Final concentrate, 65 to 70% WO_3.
Recovery: About 80%.
Cost at 25 t.p.d., $2.40 per ton (1931).

Summary. Crushing in 4 stages (2 jaw, 2 rolls) to <12-m. Oversize and undersize of 22-m. tabled separately. Middling reground and recirculated. Concentrate dried, roasted lightly to render pyrite magnetic, and cleaned on a Dings magnet.

Flotation tests using sodium carbonate, oleic acid, sodium oleate, and pine oil indicated upward of 90% recovery with 60 to 65% WO_3 concentrate.

Nevada-Massachusetts Co., Inc. Fig. 164 (*IC 6280; IC 6852*).

Location: Mill City, Nev.
Ore: Scheelite rather finely disseminated in a gangue of quartz, epidote, garnet, calcite, and pyrite
Capacity: 140 tons per 24 hr.
Assays: Feed: 0.9% WO_3; concentrate, 70 to 75% WO_3, <0.05% Cu, <0.75% S, <0.05% P, <0.035% each of As, Sb, Bi; may carry 4 to 6 oz. Ag per ton and a trace Au.
Water from neighboring wells and reclaimed from concentrate and tailing.
Labor: 9.4 tons per man-shift total.
Power: 20 hp-hr. per ton milled.
Costs (1934): $1.25 per ton milled; labor comprises 47%.



Legend for Fig. 164:

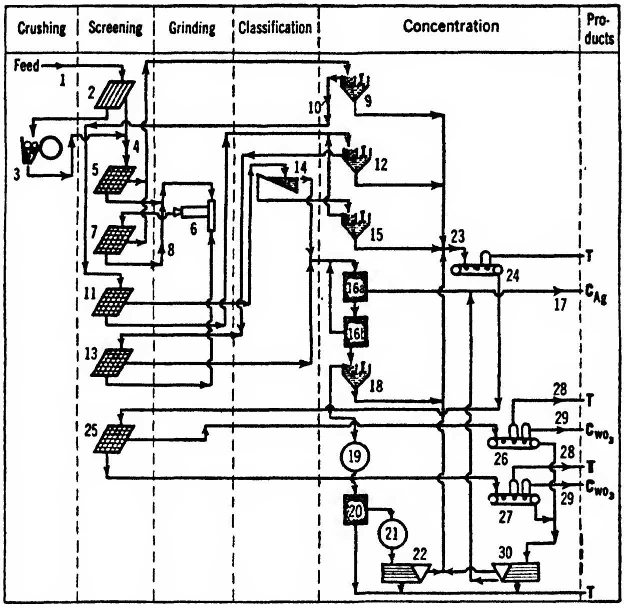
1. R.o.m. through 8-in. mine grizzly; 2 flat-bottom bins, 500-ton combined capacity; 8 @24×30-in. rack-and-pinion gates; 1 @ 24-in. variable-speed apron conveyor.
2. Grizzly, 1 1/2-in. spacing.
3. 1 @ 9×16-in. roll-jaw crusher (manganese steel wearing plate lost about 60 days).
4. 1 @ 24-in. belt conveyor; belt-bucket elevator.
5. Trommel, 9/16-in. rd. holes.
6. 1 @ 36×15-in. rolls, 63 r.p.m.
7. 1 @ 12-in. belt conveyor; hand-propelled tripper; 2@200-ton cylindrical redwood-stave bins; 2 Hammil ore feeders; 1 @ 12-in. conveyor belt.
8. Belt-bucket elevator (water added).
9. Trommel, 1/8×1/4-in. Ton-Cap screen.
10. 1 @ 36×16-in. rolls, set 1/4-in., 95 r.p.m.
11. 1 @ 24-in. Callow traveling-belt screen, 14-m. phosphor-bronze cloth.
12. 2 @ 36×16-in. rolls set close, 100 r.p.m.
13. 2 @ 1-spigot hydraulic classifiers in series; spigot products go separately to table distributors.
14. 2 Wilfley and 4 Deister-Overstrom tables on spigot product from first classifier (13) and 2 Wilfley and 3 Deister-Overstrom tables on product from second classifier (13).
15. 3 @ 8-ft. Callow cones.
16. Deslimer, spigot product to (17).
17. 2 Wilfley tables.
18. 1 @ 8-ft. Callow cone.
19. 1 Deister-Overstrom table.
20. 1 as (19).
21. 1 @ 4-ft. Callow cone.
22. 1 @ 2-cell Kraut flotation machine to remove to finer sulphides, predominantly pyrite and molybdenite.
23. Belt-bucket elevator.
24. Small Akins classifier.
25. Oil-fired rotary drier; belt-bucket elevator.
26. 1 @ 6-pole Wetherill magnetic separator; garnet must be largely rejected here as otherwise it agglomerates with other material in roasting.
27. Belt-bucket elevator; belt conveyor.
28. Rotary oil-fired roasting kiln for magnetic roast for pyrite.
29. Steel-screw conveyor with light water spray.
30. 1 as (26); the roasted magnetic pyrite is sufficiently porous to make gravity separation from scheelite possible.
31. Belt-bucket elevator; steel-screw conveyor.
32. Externally fired roaster for dead roast to drive off S and As.
33. Screw conveyor; belt-bucket elevator.
34. Type M-2 Dings magnetic separator.
35. Bucket elevator; sacking hopper.

FIG. 164. NEVADA-MASSACHUSETTS CO.

Summary. Four-stage crushing to 14-m. Discard of primary slime. Classification and tabling of sand to make rough concentrate. Sulphides roughed out by flotation. Magnetite removed by magnetic separation of dry concentrate. Residual pyrite removed after magnetic roast.

Ima Mines Corp. Fig. 165 (*IC 7230*).

Location: Patterson, Idaho.
Ore: Hübnerite, argentiferous tetrahedrite, scheelite, galena, sphalerite, chalcopyrite, and molybdenite in quartz, with minor quantities of fluorite, rhodochrosite, muscovite, and pyrite.
Capacity: 120 tons per 24 hr.
Assays: Feed: Ag, 1.85 oz. per ton; Cu, 0.2%; Pb, 0.25%; Zn, 0.2%; S, 2.1%; WO_3, 0.52%; MoS_2, 0.1%; tungsten concentrate, 66 to 67% WO_3; silver concentrate: 45 oz. Ag, 3.8% Cu, 7% Pb, 29.2% Fe, 4.8% Zn, 37.6% S, 9% insol.; tailing: 0.07 to 0.1% WO_3, 0.2 to 0.25 oz. Ag; more than 50% of WO_3 in tailing is <800-m.
Recovery: 81.2% WO_3.
Ratio of concentration: 158 : 1.
Power: Diesel and hydroelectric; CONSUMPTION, 29.5 hp-hr. per ton.
Water: From creek on property.
Costs (operating): Labor, 79.5¢; supplies, 34.6¢ (includes 16¢ for flotation reagents); power, 32.6¢; maintenance, 20.4¢.



Legend for Fig. 165:

1. 6 or 8-car trains of 16-cu. ft. cars; 3-car surge bin with rail-grizzly cover (8-in. spacing); oversize sledged through.

2. Grizzly bottom of surge bin (1), 35° slope, 1 1/2-in. spacing.

3. 1 @ 9 × 15-in. Blake-type jaw crusher, 1 1/2-in. open setting.

4. Bucket elevator; 100-ton bin; adjustable-stroke (Massco) feeder.

5. 1 @ 3 × 5-ft. Hum-mer screen, 3 1/2-m. cloth.

6. 1 @ 6 × 4 1/2-ft. grate-type ball mill, 26 r.p.m. Pulp density 55 to 60% solids. 6,000 to 7,000 lb. hardened forged-steel balls, 4-in. replacements, 2.2 lb. per ton (6 to 7 lb. with chilled cast iron). Manganese steel liners and grates; consumption: breast, 0.4 lb.; feed end, 0.05 lb.; grates, 0.03 lb. Screen tests of feed and products are given in Table 115.

7. 1 @ 24 × 36-in. Denver spiral screen, 3 1/2-m. aperture.

8. Bucket elevator.

9. 1 @ 36-in. 1-cell California-type Bendelari jig, 150 @ 5/8-in. s.p.m. Concentrate, 36 to 40% WO_3; most of the pyrite rejected.

10. 2-in. rubber-lined Wilfley pump; life of runner 4 to 6 wk. *vs.* 8 da. for Ni-hard.

11. 2 @ 3 × 5-ft. Hum-mer screens, 14-m. stainless-steel Ton-Cap (#833).

12. 1 @ 16 × 24-in. 2-cell Denver jig, 200 @ 1/4-in. s.p.m.; concentrate principally coarse pyrite, 12 to 20% WO_3.

13. 1 @ 3 × 5-ft. Hum-mer screen, 30-m. stainless-steel Ton-Cap (#433).

14. 1 @ 4 × 15-ft. rake classifier, slope 3 i.p.f., 28 r.p.m.; overflow, 15% solids.

15. 1 @ 12 × 18-in. 2-cell Denver jig, 300 @ 3/16-in. s.p.m.

16. 1 @ 8-cell No. 18 Denver Sub-A flotation machine, *a* = cells 1, 2; *b* = balance; feed, 20% solids; isopropyl xanthate, 0.15 lb. per ton, pine oil, 0.10 lb.

17. 1 @ 10-ft. thickener, 1 @ 2-ft. 4-disk filter, lead smelter. Ratio of concentration, 29 : 1.

a 1 1/2-in. nominal limiting size.

b Mill tailing with this circuit product contains 36.1% <200-m.; with mill in closed circuit with classifier (14), mill tailing was 35-m. limiting and contained 46.0% <200-m.

FIG. 165. IMA MINES CORP.

Legend for Fig. 165—Continued:

18. 2 @ 12×18-in. Denver jigs. About 15% of total recovery made here.

19. 1 @ 6-ft. conditioning tank, 15% solids; 0.25 lb. oleic acid, 0.30 lb. AC 708, 0.05 lb. Emulsol X-1 added as an emulsion.

20. 1 @ 8-cell No. 18 Denver Sub-A machine; concentrate assays 4 to 6% WO_3, balance chiefly fluorite, rhodochrosite and sericite.

21. Conditioner; 0.05 lb. H_2SO_4 added to break down froth.

22. 1 No. 6 Deister-Overstrom table with riffled-rubber deck; concentrate assays 50 to 55% WO_3, tailing 1 to 2% WO_3.

23. Dewatering box, combined concentrate, 20 to 30% WO_3; rotary drier. 1% >8-m., 16% <200-m.

24. Magnetic separator, low intensity; magnetic product is circuit iron and partly roasted pyrite.

25. Vibrating screen, 65-m. aperture.

26. 1 @ 24-in. Dings Type E 2-pole magnetic separator, 32 to 38 amp. Feed rate, 100 to 125 lb. per hr. per ft. of belt width.

27. 1 @ 12-in. Dings Type E 2-pole magnetic separator, 16 to 18 amp. Feed rate about 250 lb. per hr.

28. Rhodochrosite, siderite.

29. 95 to 97% recovery. Sacked in 100-lb. paper-lined canvas.

30. Pilot table. Concentrate about 1% of total WO_3.

Summary. One-stage crushing to 1 1/2-in., and one-stage grinding to 3 1/2-m. Rough concentration by jigging and soap flotation, with sulphides and silver skimmed out by sulphydric flotation ahead of soap flotation. Rough concentrate cleaned by magnetic concentration.

Bolivian mills. In the Bolivian tungsten ores the usual tungsten-bearing mineral is wolframite, although in some it is scheelite. Tungsten content is 2 to 4% WO_3. The usual associates are pyrite; more or less chalcopyrite; considerable bismuth, usually as the oxide; arsenopyrite; sometimes barite; rarely cassiterite; some ores contain gold and silver. Most of the mills are small, many of them worked by hand.

Hand concentration (*143 #6 J 64*) is done by breaking with single jacks to a size permitting crushing by a *quimbalete*. (This is a half cylinder of iron, shod with steel wearing plates, fitted with a two-man handle for rocking, and weighted with stones as desired. It is rocked and twisted on a layer of broken rock spread on a flat, hard surface.) The quimbalete product, usually <1/2- or <3/8-in., is sized by working it over flat screens set over boxes placed stepwise, each with successively finer screen cloth. Undersize is carried along by water and oversize removed by hand. Five or six sizes may be made between 1/2-in. and 1-mm. Final undersize is buddled and the sized products are hand jigged. The coarser jig concentrates are hand picked to remove sulphides and sulpharsenides; fines may be crudely calcined or even floated. Approximately half of the Bolivian tungsten output is thus produced.

Machine plants at the larger mines (*2 #4 FMQ 36*) comprise hand picking of run-of-mine ore, two- or three-stage crushing in jaw crusher and rolls, screening, jigging of coarser sizes with recrushing of middling, tabling of fine sands, and buddle treatment of slimes. Gravity concentrate is variously treated according to the nontungsten content; if sulphides other than pyrite are present, flotation is used to remove the bulk and the remaining concentrate is roasted to drive off the last of the S and As; pyrite is magnetized by roasting and then separated by magnets. Recoveries range from 45 to 74% in concentrates averaging close to 60% WO_3.

47. URANIUM

Uses are practically limited to glass and ceramic industries, in which sodium uranate and the U_2O_6 oxide are the usual vehicles for introducing the element. In glass or in ceramic glazes, uranium produces fluorescence, or yellow, brown, or black coloration, depending on amount and color of the added ingredient (*10 ACerS 813*). As a deoxidizer for steel, ferrouranium proved less suitable (largely because of volatility of uranium) than other and less expensive alloys (*TP 177 USBM*). Uranium has also served as catalyzer in the Haber and other nitrogen-fixation processes. The carbide U_2C_3 is strongly pyrophoric.

Ores. Pitchblende (impure U_3O_8) and carnotite (theoretically $K_2O \cdot 2\,UO_3 \cdot V_2O_5 \cdot 3H_2O$) are the only industrial sources of uranium; for occurrences of the former, see Art. 38; of the latter, Art. 48. Pitchblende concentrates from ELDORADO mines (below) are estimated to yield 800 to 900 lb. of uranium compounds per ton; those from Belgian Congo have carried as high as 60% U_3O_8, and the St. Joachimsthal concentrates are of about the same grade. In Portugal, unconcentrated pitchblende ores with as little as 1% U_3O_8 have been treated chemically for extraction of radium and uranium compounds. Carnotite ores in the Paradox Valley, Colo., as shipped to treatment plants (interested primarily in vanadium), average 2.25% U_3O_8; small pockets running up to 15 to 20% U_3O_8 are sometimes encountered, but considerable tonnages below 2% remain at the mines.

Production. Port Hope radium refinery of ELDORADO GOLD MINES produced as by-product uranium compounds: 160,660 lb. in 1935, 211,860 lb. in 1936, 546,000 lb. in 1937, and about the same amount in 1938; receipts of pitchblende concentrates in 1939 were about double those of 1938. Annual plant capacity is reported as 10,000 tons of uranium

compounds. Exports (U_3O_8 contents) of compounds produced in Belgium from Congo pitchblende have fluctuated from a low of 61,700 lb. in 1932 to a high of 330,500 lb. in 1936; the 1938 exports were 286,000 lb. The U_3O_8 equivalent of compounds made at St. Joachimsthal was 34,800 lb. in 1935; 35,400 lb. in 1936; 24,300 lb. in 1937. Portugal produced compounds containing 23,600 lb. U_3O_8 in 1936. Carnotite ores produced in U. S. were reported to contain 51,700 lb. uranium in 1938; 59,300 lb. in 1939; actual recovery not stated. The world potential resources of uranium considerably exceed present demands.

Prices. At close of 1939, sodium uranate was quoted at $1.75 to $1.80 per lb.; uranium oxide (96% U_2O_6), at $2.65 per lb. for black, $1.75 for yellow.

Treatment. Method of concentrating the pitchblende-silver ore at Eldorado, Canada, is illustrated in Fig. 166. For the decomposition and refining treatment at Port Hope, Ont., leading to the production of radium bromide, see *44 CME 362*. See also *Bul 70 USBM 104*.

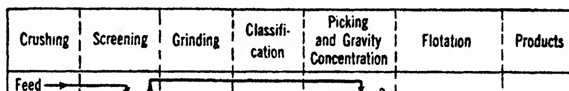
Eldorado Gold Mines, Ltd. Fig. 166 (D. A. G. Smith, Mill Supt., *139 #4 J 35*).

Location: La Bine Point, Great Bear Lake, Northwest Terr., Canada.

Ore: Pitchblende, native silver, and chalcopyrite, with various iron, cobalt, nickel, molybdenum, bismuth, lead, zinc, and manganese minerals in fine-grained siliceous altered sedimentaries and volcanic rocks, highly fractured and sheared.

Capacity: 75 tons per 24 hr.

Assays: Feed (aver. month Jan., 1938), 1.064% U_3O_8 (radium equivalent is calculated on the ratio of 3.4 parts Ra to 10^6 parts U), 26 oz. Ag per ton; concentrate: U_3O_8, 26.7%; Ag, 406 oz.; tailing, 0.25% U_3O_8.



Legend for Fig. 166:

1. Sledged through a flat grizzly of 90-lb. steel rails spaced 10 in.; 1 @ 50-ton ore bin.

2. Grizzly 3/4-in. spacing.

3. 1 @ 12×3-ft. bumping-type sorting table, actuated by an air-driven Parks Pusher.

4. 1 @ 9×15-in. Blake crusher, 3/4-in. set.

5a. 1 @ 14-in. belt conveyor; 1 @ 5×8-in. bucket elevator.

5b. Symons cone crusher.

6. 1 @ 2×4-ft. A-C vibrating screen, 1/2-in. aperture.

7. 1 @ 4×8-ft. A-C rod mill, 12,000 lb. 4-in. high-carbon-steel rods; consumption, 1.75 lb. per ton.

8. 1 @ 75-ton bin with 12-in. H-type wall feeder; 1 @ 7×12-in. bucket elevator.

9. 1 @ 2-deck A-C vibrating screen, 4- and 14-m. cloths.

9a. 1-spigot Richards hydraulic classifier.

10. 2 @ 18×24-in. James jigs, 3/32-in. slotted plate.

10a. 2 @ 18×24-in. James jigs, 0.063-in. opening.

11. 1 @ 48-m. vibrating screen.

11a. Ball mill.

12. 4 @ #6 Wilfley tables.

13. 1 @ 30-in. Akins classifier.

14. 1 @ 4×6-ft. A-C ball mill, 6,000 lb. drop-forged balls; consumption, 1.3 lb. per ton.

15. 5 Plat-O tables.

16. 1 @ 8-cell No. 15 Denver Sub-A flotation machine.

16a. Cells 1 to 4 of (16).

16b. Cells 5 to 8 of (16).

17. Thickener.

18. Conditioner.

FIG. 166. ELDORADO GOLD MINES.

Recovery: U_3O_8, 73.6%; Ag, 54.6% with flotation, 30% without.

Ratio of concentration: 27.7 : 1.

Water comes from Great Bear Lake, on the shore of which the mill is located.

Power is generated by Diesel engines from fuel costing 35¢ per gal. at the property.

Labor: Wages are $4 to $5 per day, plus board and lodging. With an average annual temperature of 17° F., labor is contracted for one year only, at the end of which time the men are sent outside, so that turnover is near 100% per year.

Transportation and distances: Mill is at mine. Concentrate is shipped by motor 1,400 mi. (with 1 @ 8-mi. and 1 @ 16-mi. portage) to Waterways, thence 300 mi. by railroad to Edmonton, Alberta, and thence 2,300 mi. by rail to the refinery at Port Hope, 60 mi. east of Toronto. Freight rate on concentrate to Waterways (1938) was \$40 per ton.

Costs: Sorting \$0.30 per ton milled; crushing, 0.44; grinding, 1.38; jigging, 0.16; tabling, 0.27; conveying, 0.49; flotation, 0.49; drying and sacking concentrate, 0.44; total, \$3.98, of which power was 35.5% and labor 30.5%.

Summary. Two-stage crushing from 10-in. to $^1/_2$-in.; stage concentration of friable U_3O_8 on jigs and tables with intervening open-circuit rod-mill grind and ball-mill grind in a circuit closed by a screen; tailing reground in a classifier-closed ball-mill circuit and floated for silver.

48. VANADIUM

Uses. Chiefly as an alloying element (alone, or in conjunction with Mo, Cr, etc.) in certain high-grade steels; automotive structural steel usually contains 0.15 to 0.20%; high-speed tool steel, 1 to 2% vanadium. Effects are to raise the yield point and ultimate strength of a suitably heat-treated carbon steel, with notably increased resistance to shock and reversed stresses. Vanadium may be introduced as ferrovanadium (of which the highest grade has 40 to 45% V and max. 0.5% C) or, in electric-furnace steel, as fused V_2O_5 (88 to 90% pure). Vanadium also refines the grain in hard aluminum alloys, such as Al-Ni-Mg. Ammonium vanadate is an excellent catalyst for oxidation reactions, as in the sulphuric acid contact process, and for dehydrogenation in various organic transformations.

Ores. In order of importance, sources of vanadium consumed in U. S. are: (1) patronite ores from Minasragra, Peru; these are indefinite mixtures of vanadium sulphide, sulphur, and asphaltic material; (2) miscellaneous mixed ores, mainly from the Southwest, in which vanadinite (lead chlorovanadate) is the usual vanadium carrier; (3) carnotite (potassium-uranium vanadate) from southwestern Colorado and adjoining parts of Utah. Roscoelite (a vandiferous mica) was formerly the chief domestic source, but the largest deposit, at Rifle, Colo., is now exhausted. The lead-zinc ores at Broken Hill, No. Rhodesia (*44 MM 88*) contain considerable descloizite and vanadinite, which go in part into the zinc concentrate. When this is dissolved for electrolytic treatment the vanadium dissolves and is precipitated as zinc or iron vanadate in purifying the zinc solution by addition of dross, calcine, or milk of lime. The vanadium is thereafter purified. Soots from oil-fired furnaces burning Mexican or Venezuelan petroleums carry noteworthy amounts of vanadium, which also occurs in numerous asphalts and (from 0.05 to 0.1%) in many bituminous coals (*19 EG 552*). Vanadium is often found in titaniferous magnetites, and is extracted from open-hearth and converter slags (reported to carry up to 10% V) at steel works utilizing the Dogger hematite ores of south Germany (containing 0.1% V) or the Lorraine minette ores (0.07% V). In Italy, some vanadium is recovered from the caustic-soda solutions in the Bayer process for purifying bauxite.

Production. World output of vanadium contained in ore concentrates or oxide was 2,963 met. tons in 1939 (2,669 tons in 1938), of which a little over one-third came from Peru (all exported to U. S.) and nearly one-third was produced in U. S.; S. W. Africa and No. Rhodesia were the largest other recorded contributors that year, but Mexico produced 147 tons. Of the domestic output (V contents) in 1939, 206,510 lb. was in oxide produced from carnotite ores, and 1,777, 560 lb. in concentrated vanadium minerals from mixed ores. Peruvian product includes some hand-sorted raw ore (11% V_2O_5) but is mainly a calcine (22% V_2O_5); combined exports in 1939 were 14,477 met. tons containing 1,017 tons V. Rhodesian material, since 1937, has been exclusively the fused oxide (formerly some concentrates); the 1939 output of 674 long tons (containing 855,960 lb. V) was derived from 58,308 long tons of ore averaging 1.41% V_2O_5. Otavi district, S. W. Africa, in the 4 years 1936–1939, exported an annual average of 4,890 long tons of table concentrates of vanadinite and descloizite averaging 19.75% V_2O_5. Mexican product is mainly vanadinite concentrate.

Prices. Nominal quotation (the larger producers also being consumers) on vanadium concentrates in 1939 was $27^1/_2$¢ per lb. of V_2O_5 content. On dried or fused oxide, \$1.10 per lb. V_2O_5. On ferrovanadium, \$2.70 to \$2.90 per lb. V.

Treatment. At Minasragra, Peru, higher-grade ores are hand-sorted, a picked product at about 11% V_2O_5 being shipped. Rejects from hand-sorting, and lower-grade mine ores, are crushed to $^1/_4$-in. and calcined, yielding an ash carrying about 22% V_2O_5, for shipment. Final electric-furnace reduction to ferrovanadium is conducted at Bridgeville, Pa. Vanadium ores of the Paradox Valley district, Colorado, consist of soft sandstone with shaly layers impregnated with a considerable variety of vanadium-uranium minerals, chiefly carnotite. Carbonaceous matter frequently accompanies the ores, which occur always in scattered pockets. Ore is hand-sorted at the mines, that containing less than 2% V_2O_5

seldom being shipped unless close to the reduction works. Because of the excessive friability of carnotite, mechanical concentration has not proved feasible, owing to losses in slime. Treatment comprises roasting of the crushed ore with NaCl and Na_2Co_3, leaching with water to dissolve Na_3VO_4, neutralization with H_2SO_4, and heating to precipitate V_2O_5. The alkaline solution of vanadium may be neutralized with $FeSO_4$, yielding a mixture of V_2O_5 and $Fe(OH)_2$. For concentration of descloizite ores at Broken Hill, Rhodesia, see Fig. 167. Chemical extraction of the Rhodesian concentrates and some of the coarser tailings (all being reduced to <200-m.) is described at *136 J 489*.

Rhodesia Broken Hill Development Co. Fig. 167 (*136 J 489*).

Location: Broken Hill, No. Rhodesia, So. Africa.

Ore: Brecciated and decomposed material resembling sandy clay; vanadium mineral is chiefly descloizite with some vanadinite and occasionally troublesome amounts of zinc silicates. For geological details, see *36 MM 177; 42 MM 47*.

Assays: Average ore to mill, 3% V_2O_5. Table concentrate, 16.5%. Mixed slime concentrate and finishing-table tailing (to leaching plant), 8.5%.

13. 16.5% V_2O_5.
14. 8.5% V_2O_5.

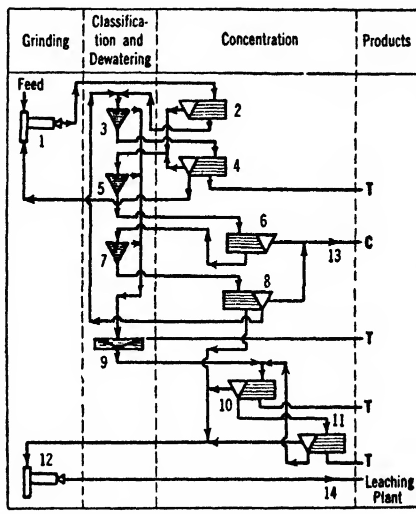

FIG. 167. RHODESIA BROKEN HILL DEVELOPMENT CO.

Summary. Ball-milling to table size; rough concentrate cleaned on tables; rough tailing classified and retabled at graduated sizes; middlings recirculated, but only coarsest recrushed. Since a large part of final recovery is to be made by leaching, the chief purpose of this mill is to eliminate low-grade tailing. Fig. 167 shows the plan as operating in 1935; after 1937, production of concentrate for shipment was discontinued, the entire output of vanadium thereafter being extracted by leaching and reduced to fused oxide.

49. ZIRCONIUM

Uses. Chiefly as degassifier, scavenger, and desulphidizer of high-grade carbon steels, in all three of which functions it has certain advantages over other elements used for the same purposes; it is said to add nothing as an alloying constituent. It may be introduced either as zirconium-ferrosilicon (9 to 12% Zr) or as silicon-zirconium (35 to 40% Zr, 6 to 10% Fe); both alloys are electric-furnace products. Alloys of zirconium with Ni, Co, Al, and Mg have found uses in nonferrous metallurgy. Zirconium oxide, natural or artificial, has exceptional refractory power, both as to temperature and reagents; it is formed into brick, plastic cement, and various laboratory utensils. The oxide is considered superior to that of tin in production of enamels for steel vessels, and when added to glass it affords exceptional toughness and heat resistance. Powdered zirconium has some advantages over magnesium in flash-light mixtures.

Ores. Two industrial minerals are (*a*) baddeleyite (ZrO_2) from massive deposits in the Caldas region, States of São Paulo and Minas Geraes, Brazil; ZIRKITE is an indefinite mixture of this mineral with zircon; as shipped, baddeleyite averages about 97%, whereas zirkite ranges from 70 to 90% ZrO_2. (*b*) Zircon ($ZrO_2 \cdot SiO_2$) is a common constituent of

alluvial and beach sands, often associated with ilmenite, rutile, and monazite, in the productive districts, of which the more important are the shores of Brazil between Rio de Janeiro and Balvia, particularly near Victoria, where the cleaned product (mainly monazite) carries 21% zircon; the shores of Travancore, southern India, centering at Quilon and Colachel, where zircon is a by-product in recovery of ilmenite and monazite; large shipments of Indian zircon have averaged 66.8% ZrO_2, 31.5% SiO_2, 0.84% TiO_2, 0.08% Fe, 0.07% P_2O_5; the eastern shore of New South Wales, immediately south of Byron Bay, where beds of black sand with maximum dimensions 3 to 4 ft. in thickness, 80 ft. in width, and a mile in length, may contain 45 to 75% zircon, 10 to 30% rutile, 10 to 20% ilmenite; garnet, cassiterite, and monazite are accessories (*31 CEMR 216*). A somewhat similar deposit was worked in 1922–1928 (mainly for ilmenite) for 11 miles along Pablo Beach, north of St. Augustine, Fla.; zircon constituted about 20% of the concentrated products. Some zircon was recovered in 1937 from sluice boxes on the KAUFIELD dredge, Lincoln, Calif.

Production. World output of zirconium ores fluctuates widely, but totaled 8,900 long tons in 1937, of which New South Wales contributed more than half; India and Brazil are the only other important producers. In 1937, U. S. imported 8,000 long tons, of which 6,658 tons came from Australia and the rest about equally from India and Brazil; 1938 imports fell to less than one-fourth those of 1937. Annual imports of zirconium ferroalloys (all from Norway) averaged 111 long tons in 1937–1938.

Prices, 1938–1939, were steady at $55 per short ton of ore with 55% ZrO_2, f.o.b. Atlantic ports. Powdered Zr metal, $7 per lb.; Fe-Si-Zr alloys (12 to 15% Zr), $97.50 to $102.50 per long ton; (35 to 40% Zr) 14 to 16¢ per lb.

Treatment. In Brazil, some of the interior deposits consist of lumps of zirkite embedded in clay from which, after sun-drying, they are separated on coarse screens; the beach sands are separated magnetically into ilmenite, zircon, and monazite. At Quilon, India, the black sands, occurring both on the beach and (under dune sand) for some distance inland, are first screened and dried; magnetic separators with comparatively weak fields then remove most of the ilmenite, residues being treated on both wet and dry shaking tables for rough separation of zircon, rutile, garnet, and monazite. Products are finished by magnetic and electrostatic machines, zircon being the nonmagnetic discard from a Wetherill. At Byron Bay, N. S. W., zircon is separated from an ilmenite-rutile mixture by flotation, yielding a product 99.1% pure zircon (ZrO_2, 66.4%). Table 116 gives screen analyses of the several regular products from this operation. On Pablo Beach, Fla., the sand, averaging about 20% heavy minerals, was first passed over 18 Deister-Overstrom tables, yielding a mixed concentrate comprising 55% ilmenite, 20% zircon, 6% rutile, 2% monazite, 14% staurolite and epidote, and 3% quartz. After the sand was dried a magnetic separator lifted a clean ilmenite concentrate; residue was separated by Huff electrostatic machines into additional ilmenite, iron silicates, monazite, and a rutile-zircon product which, after further cleaning on a wet table, was subdivided electrostatically, rutile being a better conductor than zircon.

Table 116. Size analyses of finished beach-sand products, Byron Bay, N. S. W.

50. SELLING METALLIC ORES AND CONCENTRATES

Revised by

Paul M. Tyler

The great majority of mining companies sell the ore or concentrate that they produce to processors who finish the extraction of the metal. This is particularly true of the commoner metals other than gold, aluminum, and iron. Gold is often recovered at the company milling plant in bullion form salable directly to the mint (p. 262). Aluminum and iron ores are usually carried to manufactured metal by the mine owner, although the mining, smelting, and manufacturing companies are ordinarily separate corporate entities, and a long haul may intervene between mine and smelter. Similar integration is found in the cases of copper, lead, and zinc, but much less frequently. The normal situation with these latter metals, however, as also with the precious metals, with tin, and with the iron-alloy metals, is for the miner to concentrate the ore into a smaller bulk of such composition as gives

maximum monetary yield when the buying schedule, freight, tailing loss, and milling cost are taken into account collectively.

The usual buyers are smelters and custom mills. When markets are glutted or unsettled both kinds of buyers may refuse to purchase, but treat the product at an agreed per-ton charge, either on a consignment to sell when, as, and if possible, or with return of product to the miner, who must then find his own market.

Custom mills are built to treat a composite of the ores in the district which they serve. The district is usually small in area, because freight quickly eats up all possible profit on shipments of raw ore, despite that tariffs are normally lower for low-grade ores. Recoveries tend to be lower in custom mills than in company mills, owing to changing character of feed, even when elaborate facilities for mixing feeds are available; this difficulty is, of course, accentuated when ores are run through individually. Many smelters maintain custom mills.

Milling charges depend upon the kind of ore, the size and frequency of shipment, the extent of segregation required, whether the ore is purchased by the milling plant, whether the mill is at a smelter, the number of unusual conditions in the transaction, and the extent of competition. Most custom mills are for treatment of gold- and silver-bearing ores; the following OPEN SCHEDULE is characteristic of the type of tender by such mills in the western U. S. to ordinary sellers; better terms can be obtained by large and regular shippers:

Flat charge (1938) covering sampling, assaying and milling, when segregation is not required:

Value per ton, $	<8	8 to 10	10 to 15	15 to 20	20 to 40	>40
Charge per ton, $	2.50	3	4	4.50	5.50	6

Small lots (<10-ton) must pay an additional $5 sampling charge; if the lot is less than carload, add $2.50; if sacked, add 10¢ per ton; if frozen, add 10¢ per ton; if wet (>10% H_2O), add 5¢ per ton per 1% excess. Resampling of <10-ton lots costs $5; larger lots more but not in proportion; such resampling must be demanded promptly. Check and umpire assays must be paid for by shipper.

Settlement is made for gold, silver, and sulphide lead only.

Gold scale is:

Oz. per ton	<0.02	0.02 to 0.5	0.05 to 5	5 to 10		>10		
$ per oz. *d*	0	32.26	32.76	32.76 *a*	33.12 *b*	32.76 *a*	33.12 *c*	33.47 *b*

a First 5 oz.
b Balance.
c Second 5 oz.
d Deduct $1 per oz. for truck shipments or lots <10-ton.

Silver scale is:

Oz. per ton	<1	1 to 5	5 to 10	10 to 20	20 to 50	50 to 100	>100
Per cent. paid for	0	50	65	75	85	90	95

Payment is at market of day preceding settlement (excluding fractions of a cent and with a deduction of 2.5¢ per oz. for excess over 100 oz.) except as price is modified by political manipulation.

Lead: Sulphide lead only is paid for, and then only when in crude ore and in excess of 3%; settlement is at 80% of wet assay less 1%; price is New York quotation for the day preceding settlement date less 2.5¢ per lb.

Limitations: Ores containing >3% of copper or zinc or >0.2% oxidized Cu not accepted. Payment of freight by shipper must be assured to the satisfaction of buyer.

Smelters have a more difficult problem in the purchase of base-metal ores with or without a precious-metal content; consequently their schedules of charges and methods of payment are more complicated than those of custom mills. The smelter buys ores on the basis of the agreed assay, paying for valuable metals contained therein at prices current in principal metal-market centers, either at date of purchase or at some agreed date thereafter meant to be the probable date of sale, less a charge covering the cost of treatment and profit thereon. The treatment charge must include the cost of delivering ore to the smelter, sampling, smelting, freight on crude metal to the refinery, refining, selling, and a carrying charge on metal from the time of purchase to the time of disposal. Various methods of assessing these charges and the profit on operations are followed. In the case of some metals all is included in a treatment charge; in other cases a part only, namely, smelting, is included in the base treatment charge, the balance being taken care of in the price at which metal is paid for after certain deductions from the market price. All methods have as the fundamental basis of charge the cost of the items above enumerated.

A comprehensive form of estimate sheet used by a smelter as a basis for contract (*Ed. 3 Peele 32–09*) is shown in Table 117. Used in connection with prices quoted in published schedules, it constitutes a valuable check list for the seller to use for his own estimates.

Notes on page 259.

Footnotes for Table 118:

1 Payments on gold are based on new mint price of \$35 per oz (net \$34.9125)
2 Payments on silver are based on new mint price for new American-mined ore at 64.64¢ per oz
3 Payments on lead are based on N Y quotation for common desilverized lead
4 Payments on copper are based on the *Eng & Min Jour* quotations
5 Less a deduction of 1 1/2¢ per oz
6 Nothing paid for lead less than 5% wet assay
7 Nothing paid for copper less than 1/2%
8 Add 10% to base charge for excess value over \$25 per ton
9 0.1% of wet-lead assay is free
10 Pay for all at 6¢ per unit
11 Pay for all at 5¢ per unit, if 5% or over
12 Add 10¢ to base charge for each unit of lead under 30% and deduct 10¢ for each unit over 30%
13 Siliceous ore schedule for ores and concentrates having excess of iron are identical, except that treatment charge is a flat \$5 per ton
14 Nothing paid for copper less than 1%
15 No credit
16 Schedule for gold concentrates
17 Add 10¢ per ton per unit of iron short of 25 units excess over insoluble
18 Schedule for crude siliceous gold ore
19 Add 10% to base charge for excess value over \$35 per ton
20 1934 schedule for irony ores and concentrates applies only to ores and concentrates containing 20% or more of iron excess over insoluble
21 Excess over insoluble, all at 10¢ per unit, not to exceed \$3 per ton
22 Crude-ore open schedule
23 When lead is over 9¢ per lb, deduct 25% of excess
24 When copper is over 15¢ per lb, deduct 25% of excess
25 Pay for iron plus manganese at 5¢ per unit, but credit is not to exceed charge for insoluble
26 All at 8¢ per unit, if 10% or over
27 Add 25% of gross value to base treatment charge, when value is between \$8 and \$10
28 Add 10% of gross value to base charge, when value is between \$10 and \$50
29 1934 siliceous-ore special for ores with 50% excess insoluble
30 On direct smelting ores containing over 5 oz gold per ton, price per oz for the excess will be left to mutual agreement between buyer and shipper
31 No payment for lead under 3% dry assay
32 Minimum deduction
33 All at 6¢ per unit
34 Based on 30% dry lead assay. Debit 10¢ for each unit under 30% and credit 10¢ for each unit above 30%
35 Midvale smelter reserves right to reject any shipment containing more than 0.1% bismuth
36 Lead ore open schedule
37 Ore over 35 oz per ton, deduct 2¢ per oz
38 No payment for copper under 1%, or when quotation is 8¢ per lb or less
39 Based on 50% lead. Add 10¢ per unit when over 50%, and deduct 10¢ per unit when under 50%
40 Penalty applies only to ore under 20% lead: no penalty for ore of 20% or over
41 Siliceous-ore open schedule: ores containing no lead, or under 5% for which no payment is made (lead determined by wet method less deduction of 1 1/4 units)
42 Between \$20 and \$35, \$7 per ton; from \$35 to \$50, \$7.50; from \$50 to \$75, \$8; from \$75 to \$100, \$8.50; over \$100, \$9 per ton

Smelter Schedules

Smelter open schedules are published tenders by the smelter to purchase or treat ores and concentrates under stated conditions as to price and other items. The elements are (*a*) the treatment charge; (*b*) penalties; (*c*) payments.

Treatment charge is the proper and apparent core of all open schedules. It covers labor, fuel, supplies; interest on invested and operating capital; charges for obsolescence, depreciation, insurance, and taxes; plant supervision; office work (including ever-increasing and expensive reports to the Government—*Ed.*); selling, management, and, politics permitting, some profit. Actual cost of treatment is generally less than \$5 per ton at lead smelters and \$3 at copper smelters. Published base treatment charges are usually definitely higher than these figures, and graduated upward for low-grade materials. Typical charges at lead smelters (1936) as compiled by Gardner (*IC 6926*) are shown in Table 118. At copper smelters the charge is \$2.50 to \$6 per ton on products of gross value below \$100, and \$8 to \$15 for gross value above \$100 (*Ed. 3 Peele 32-14*). Zinc smelters base differently; schedules do not ordinarily state a treatment charge.

Penalties are imposed for ore constituents which add to the difficulties and costs of smelting. They are normally graduated according to the content of unwanted material or the deficiency of desired material.

It is necessary in lead and copper smelting that the slag be sufficiently fluid to allow the metal or matte to settle out freely, and to permit easy discharge of slag. To obtain the desired fluidity the slag must have a particular (Fe : Ca : SiO_2) ratio. The basic smelter charge is founded upon the cost of smelting a charge of such composition as will produce the desired slag. If the ore to be treated will not

do this, it is necessary to make up any deficiency. In districts where the majority of the ores sent to the smelter are siliceous, iron or lime, or both, must be added. In order to cover the cost of addition of such substances, a penalty is imposed for silica present in the ore bought. If, on the other hand, the prevailing ores of the district are calcitic or ferruginous, silica must be added and iron and lime are penalized to make up the cost of such addition. When silica is penalized, iron and lime are usually granted a corresponding bonus, and *vice versa*.

Penalties and bonuses are quoted at so much per unit. A UNIT is 1% or 20 lb. per ton (22.4 lb. per long ton). SILICA PENALTY normally ranges from 5 to 15¢ per unit for all excess over a stated amount, which should be that required for a self-fluxing charge; IRON BONUS ranges from 5 to 10¢ per unit in excess. A bonus is not ordinarily paid for lime, but should be, especially when silica is penalized, since one part of iron or lime ordinarily fluxes one part of silica. When siliceous ores are wanted at a smelter a flat rate may be made for their treatment in place of allowing a bonus for silica. In this case the charge usually increases with the grade of ore, as is the case at custom mills, and for the same reason. Table 119 shows such a schedule.

Table 119. Flat schedule for siliceous ores in Colorado district (1914)

Value of ore per ton	Charge per ton for treatment	Value of ore per ton	Charge per ton for treatment
$14 and less...	$5.00	$35 to $40.....	$8.00
14 to 20.....	6.00	40 to 45.....	8.50
20 to 25.....	6.50	45 to 50.....	9.00
25 to 30.....	7.00	50 and more..	10.00
30 to 35.....	7.50		

In lead smelting, the formation of any considerable amount of matte is undesirable and consequently it is necessary to roast sulphide ores prior to their introduction into the smelting furnace. For this reason sulphur, being a source of expense to the smelter, must be paid for by the ore seller and is usually charged in the form of a penalty for sulphur. The usual contract penalizes SULPHUR in excess of 2 or 3%, ordinarily at a rate of 15 to 25¢ per unit. Sulphur is not penalized in copper smelting, since here it is desirable. ZINC, in lead and copper ores, causes slag to be thick and viscous, thus increasing metal losses therein and lowering furnace capacity. It also causes fumes that foul the furnace walls, and, by volatilization, causes losses of other metals. For this reason, zinc above a certain amount is frequently penalized. For zinc penalties in lead ores see Table 118. For copper ores there is no zinc penalty at many smelters; some impose the 30¢ penalty for excesses above 6 units. ARSENIC is decidedly undesirable in lead smelting and for that reason all over 1% is commonly penalized; ANTIMONY and TIN are also objectionable; the penalty for these three elements combined may run as high as $1 per unit for the excess over 0.5%. BISMUTH hardens lead and discolors white-lead pigments made from bismuth-bearing pig. It is, therefore, penalized heavily (Table 118) and may cause refusal to accept. Penalties for these four elements are less frequently imposed in copper smelting; when penalties are imposed they are about the same as is lead smelting. IRON is highly undesirable in zinc smelting; more than 10% makes the ore substantially unfit for treatment. The penalty for iron is normally imposed by setting a certain price for zinc ore of a given zinc content and penalizing it so much per unit for each unit below standard. In such cases a corresponding bonus is ordinarily given for each unit of zinc above standard.

Crude gold or silver ores shipped to smelters are typically siliceous; concentrates, on the other hand, generally contain an excess of iron. Ores that contain too little lead or copper to serve as collectors of the precious metals in smelting are termed DRY ORES. Highly siliceous ores (60% upward of SiO_2) are valued by copper smelters for use in converters, whereas they are highly penalized by lead smelters. In certain districts, however, siliceous ores are smelted on a flat schedule designed to encourage mining and maintain a flow of ore to the smelter. In Leadville, Colo., the treatment charges per ton are scaled from $5 for such ores worth $14 or less a ton to $10 for ores worth $50 or more per ton.

Payments for a given metal differ materially according to the kind of smelter buying, and, of course, to the character of material shipped. Thus a lead smelter may pay about 4¢ per pound less for copper in a given ore or concentrate than a copper smelter, but the latter will pay for only half the lead at 2¢ less per pound.

Example (after Lamb, *Tref Bul. DECO 3713-B*). A complex sulphide ore assaying 0.45 oz. Au, 9.6 oz. Ag, 6.7% Cu, 3.4% Pb, 5.1% Zn, 18.5% Fe, and 38.4% insoluble can be handled in at least four ways as shown in Table 120.

Payments by the smelter are rarely, if ever, based on the full amount of a given metal in the product shipped, as shown by assay, nor on the full market value of the metal at the time of settlement. The first difference is supposed to take care of losses in treatment. The second deduction is to cover freight on base bullion and the cost of refining it, the cost of recovery of by-products, selling, and it serves also as a hedge on the course of the market between settlement date and sale. Payment deductions and penalties are, in most cases, the sources of smelter profits. Lack of change over long periods would normally be taken as a sign that the advantages accruing from technological improvement were not being divided with the shipper voluntarily, and that there was a considerable cushion for bargaining. However, the fact that deductions have remained substantially the same over the last 20 years in a competitive field, despite reductions in operating costs that have occurred

in the face of rise in wages and union slow-downs, reflects the increasing costs of political impositions [*Ed.*]. Some concessions are available to large shippers who are in a position to bargain, but in general both producers and consumers must suffer.

Losses include metal in slags, either as shot or combined, volatilization and dusting, spill, and refinery losses. Walker (*Ed. 1, Peele*) gives the following metal losses in smelting and refining: lead 4 to 15%, depending upon the grade of ore and its refractoriness; the lower limit is for a charge carrying about 40% lead; the higher, for one carrying 10 to 12%. Copper loss sometimes reaches 30% in lead smelting. In smelting copper ore the loss varies with the percentage of copper, but is always much less than the loss of lead in lead smelting. Silver loss is normally not over 2 to 5%. Gold loss is generally inconsiderable. Fulton (*TP 83 USBM*) quotes actual losses as follows: In LEAD SMELTING: lead, 5 to 20% of contents, the low figure on a high-lead charge, 30 to 35% Pb or upward, and containing but a small amount of roasted material; the higher, on a charge containing less than 10% Pb or a large amount of roasted material. Normal loss with a charge containing 10 to 15% Pb is 8 to 11%. Copper, 1 1/2 to 4 lb. per ton of charge. Silver, 1.5% loss to 1.75% gain. The gain is, of course, apparent only, and follows from the bookkeeping practice of charging the smelter with a silver only in those ores containing more than a certain minimum amount. Gold, 0.3% loss to 4.5% gain. The same explanation applies to the apparent gain. In COPPER SMELTING: copper, 3 to 11 lb. per ton of ore smelted or 5 to 15% on the copper present, the higher figure on the lower grade ore. Silver, 0.5 to 10% of contents. Gold, 1.5% loss to 4% gain. Barbour (*92 J 314*) states that the usual zinc loss in zinc smelting is about 12.5%.

Table 120. Effect of treatment and marketing on returns from a complex ore

Treatment and product	Tons shipped	Sold to	Net return per ton *a*	
			As shipped	Based on crude ore
No treatment:				
Crude ore........	1.0	Lead smelter	$14.10	$14.10
Crude ore........	1.0	Copper smelter	20.05	20.05

Zn concentrate *e*..	0.054	Zinc smelter	30.70	1.65
Total....	0.333			$30.80

a Less hauling, freight, and treatment charges. Market prices: Au, $35 per oz.; Ag, $0.7757 per oz.; Cu, $0.12 per lb.; Pb, $0.06 per lb.; and Zn, $0.06 per lb.

b 0.24 oz. Au and 0.78 oz. Ag per ton crude ore.

c 0.3 oz. Au; 14.4 oz. Ag; 27.8% Cu; 1.3% Pb; 2.5% Zn; 29.1% Fe; 2.9% insol.

d 1.6 oz. Au; 61.9 oz. Ag; 5.0% Cu; 44.8% Pb; 3.1% Zn; 3.0% Fe; 8% insol.

e 0.12 oz. Au; 4.4 oz. Ag; 0.5% Cu; 0.2% Pb; 63.2% Zn; 1.1% Fe; 2.0% insol.

Lead losses are sometimes taken care of, wholly or in part, by basing payment for lead on a fire assay. This practice is based on the assumption that fire assaying is smelting on a small scale and recovers the same amount of lead that will be recovered in the furnace. The fire assay for lead runs about 0.5 to 1% below the wet assay unless such metals as zinc, copper, antimony, bismuth, or arsenic are present, in which case fire assay may run high. To cover this contingency some contracts call for wet analysis of the button obtained by fire assay and base lead payment on the assay thus obtained. Common practice at present is to make a wet analysis and deduct therefrom 1 to 1.5%, calling this DRY ASSAY or FIRE ASSAY and using the latter as basis for settlement. On the basis of a 10% loss of lead in smelting, a 1.5% deduction from the wet assay more than covers the loss on ores carrying less than 15% lead but does not cover with higher-grade ores. However, the loss on higher-grade ores is a smaller percentage of the total lead present and it is probable, therefore, that a deduction of 1.5% from the wet assay more than covers loss in all cases of gold lead-smelting practice. Lead losses are further taken care of by paying for less than the whole amount of lead determined by either method of assay as, for instance, by paying for 90% of the lead determined by dry assay. Further, the deduction from the market price is oftentimes made greater than the cost of freight on crude metal, refining, and selling, in order to further insure the smelter against losses.

Copper losses are similarly taken care of, although the use of the dry assay is less common than with lead. DRY COPPER means from 0.75 to 1.5% less than the wet assay.

Gold and silver losses are provided for by deducting up to 5% of the assay value for gold and 5 to 10% for silver, or by paying less than the full price for all of the metal present, or both.

Freight on crude metal, refining, and selling. The costs (1926) of these various operations, according to Walker (*Peele*), were: For refining lead, $8 to $12 per ton of bullion; for converting copper matte, about $20 per ton of blister copper produced; for refining copper, $15 to $23 per ton of bullion. The usual deduction in copper contracts is 2.5 to 3¢ per lb. from the New York quotation for electrolytic copper. Similarly from 1 to 1 1/2¢ per lb. is deducted from the lead price.

Gold payments, formerly based on $20.67 per oz., have been based since 1933 on the realized mint price of $34.9125 per oz. ($35 less $0.0875 refining charge). Both lead and copper smelters usually pay for all Au over about 0.03 oz. per ton; the minimum ranges from 0.02 to 0.05; some contracts deduct the minimum from the settlement assay. The price commonly varies according to the Au assay (see Table 118).

Silver payments have generally been based in North America on the New York (Handy and Harman) quotations for the week during which the last car of the lot arrives at the smelter, but under the Silver Purchase Act domestically mined silver (accompanied by the necessary affidavits) is paid for on the basis of the realized mint price. Smelters usually deduct 1 oz. (sometimes only 0.5 oz.) per ton from the assay and pay for 95% of the balance, sometimes making an additional deduction on nondomestic ores from the market price.

Zinc and antimony smelters often make no payment for Ag or Au and those that do, deduct heavily because their losses in recovering precious metals are higher than those of copper or lead smelters.

Native placer gold and bullion from amalgamation or cyanidation plants can be deposited at the United States Assay Offices in New York and Seattle or at the mints at Philadelphia, San Francisco, Denver, and New Orleans and will be paid for usually within 3 to 5 days at the market price of these metals less specified refining charges, provided the gold, or gold and silver content is 20% or more. Silver, free from gold, will not, necessarily, be accepted unless needed for coinage or under some special provisions (*e.g.*, the Silver Purchase Act). No allowance is made for platinum or base metals contained in bullion.

Lead. Galena concentrates in the Tri-State district are sold by the ton to local smelter buyers at a competitive price, with adjustment to cover assay, and variations from the normal 80%-Pb base product. Western lead-smelter contracts show considerable variety in lead payments. Some pay at specified prices per unit, which are raised if the New York price rises above a stated minimum; the unit prices also increase on a sliding scale with the Pb content. Another form pays for 90% of the fire assay at 90% of the New York price, or at a deduction of 1¢ to 1 $^3/_4$¢ per lb. from New York quotations for common desilverized metal. Actually few analyses are made by fire assay, but lead smelters nearly always deduct 1 to 1.5% from the wet assay in figuring the Pb content. Less than 5% of Pb is rarely paid for, but a bonus of perhaps 15¢ per unit is sometimes allowed for Pb under 5%. Copper smelters, as previously noted, pay usually for only 50% of the lead (wet assay) and deduct as much as 50% from the price. See also the various summaries in Table 118.

Copper. Payments for Cu are usually on fire assay, or on wet assay less 1 to 1.5%, and are generally based on *Engineering and Mining Journal* quotations for electrolytic cathodes averaged for the week, less a deduction of 2.5 to 3¢ per lb.

A Midvale contract, for example, deducts 15 lb. per ton and pays for the balance at 3.0¢ less than New York price, plus a further deduction of 10%; base treatment charge is $5.00 per ton, scaling upward to $7.00 on ores worth $30 or more per ton. Zn over 6% is penalized at 30¢ per unit of excess. Sb and As combined: 2% free; excess penalized at 50¢ per unit.

Zinc. Middle West zinc ores are usually bought outright by smelters or their representatives on a base price for 60% sulphide or 30% carbonate ore with adjustment (usually $1 a unit) for assay variations above and below this base. Penalties may be charged for Fe, CaO, or other undesirable elements.

A Western zinc plant (*Tref DECO 3713-B*) pays for 82% of the Zn content at the St. Louis price for Prime Western less 0.275¢ per lb., with further deduction if Zn content is under 45%. Au, Ag, Cu, and Pb are paid for on the basis of 65% of content, with usual deductions from market prices. Base treatment charge is $19 a ton plus or minus $3 a ton for each 1¢ change in market price of slab zinc over or under 4¢.

Moisture. Most mineral products are purchased on a dry basis. Freight is charged on gross wet weight at time of shipment. Ore and concentrate shipped in open cars may lose or gain moisture in transit, and, since moisture samples are taken by the buyer as soon as possible after weighing at the receiving point, shippers have no means of protesting moisture assays of the buyer unless their own representative is present at the time the moisture sample is taken. Smelters often make minimum deduction of 1% for moisture, even if ore happens to be almost dry, to cover dusting losses. Occasionally wet ores (>6 to 10% moisture) are penalized because they hang up in bins and freeze in cold weather. Table concentrates and filtered flotation concentrates usually carry 8 to 15% moisture; they should be dried to 5% or less before shipping any considerable distance.

Sampling. For discussion of methods see Sec. 19. Moisture samples should be taken as soon as possible after the ore is weighed in, especially if in open cars; wetting after

weighing in and before sampling results in a charge against the lot as weighed of too much moisture and thus operates against the shipper. Sampling for chemical analysis should yield four final pulp samples of about 2 lb. each; one for the smelter laboratory, one for the shipper, one for umpire, and one as an emergency reserve for either of the three. Splitting limits between mine and smelter assays are given in Sec. 19, Art. 7. When umpiring is resorted to, the umpire's result is usually taken when it lies between the disputed results. The disputed result nearest the umpire's is taken when the umpire's result lies outside the disputed results. Analysis should determine not only the valuable metals but also constituents such as iron, lime, silica, magnesia, alumina, and sulphur, upon which the common bonuses and penalties are based, and also any other substances that are specified in special instances. Analyses to determine these constituents should be just as carefully made as those for the valuable metals, as the penalty or bonus may make an important difference in the value of the ore. Silica should be determined by fusion rather than as "insoluble," as the latter is almost invariably high, as much as 15 to 20% with ores of high insoluble content and frequently 4 to 6% (*TP 83 USBM*). It is sometimes insisted also that iron and lime be determined by fusion. Ores that must be roasted and therefore crushed fine are usually sampled by machine, but those that are to be smelted in a blast furnace directly, such as oxide ores, are commonly sampled manually. The cost of sampling varies with the kind of ore and the method; it should rarely exceed $1.00 per ton and averages near $0.50 per ton with wages for common labor at $4.00 per day. On shipments less than 10 tons a sampling charge, usually $5, is made; on larger shipments the sampling cost is absorbed in other charges. The shipper or his representative should be present to watch the sampling and receive the sample. Smaller shippers may agree with the seller upon an umpire to represent both parties either in the sampling or assaying or both. Absence of seller or his representative when sampling is done is usually deemed a waiver of right to protest sampling, and seller's failure to make or submit an analysis may cause buyer's assay to govern.

Buyer's weights or railroad weights are usually accepted, depending upon the contract.

Metallics. Settlements for ores that yield appreciable amounts of metallics (gold and silver too coarse to pass the screen used in preparing pulp) are notoriously open to disputes. Metallics cannot be split equally between four pulp samples, hence there is no opportunity for check assay. Moreover, the loss in handling even a few particles of gold makes an appreciable difference in calculated value per ton and neither buyer nor seller is likely to be satisfied by the results. Usually it is to the advantage of all concerned to take out coarse gold or silver and sell it as bullion to the mint.

Dust losses and spillage. Ores and (more especially) fine concentrates that are too dry are likely to show loss in transit from dusting. The finer the concentrate the more water should be left in to avoid such losses. Rich concentrate should be packed in double sacks, although many smelters make a handling charge of 50¢ per ton for ore shipped in sacks. Cloth sacks are returnable to shipper. Powdered minerals are packed in paper bags or other containers. If concentrates or other fine material is shipped in bulk, in boxcars or trucks, care must be taken to cover all cracks in floors or sides; lining with heavy paper is usually advisable. Shipments in trucks should always be covered and tailboards should be securely fastened.

Freight and trucking. Trucking may be cheaper than rail transport for small lots and short distances, because minimum carloads are defined as 20 to 50 tons, depending upon the railroad and the ore, and rates for less than carload lots are high. Average costs per ton where trucks are kept busy, loaded from chutes, and dumped into car or bin without shoveling, in gold-mining districts of Arizona and California, as given by Gardner (*6891 IC 40*) ranged from 35¢ for under 1 mile, 12¢ for 2 to 5 miles, and 5¢ for 20 to 100 miles in 1935. Commodity rates usually are established by railroads when regular shipments are to be made. On Western roads the average base rate is about 1¢ per ton-mile, though large tonnages of low-grade ore move for as low as 0.5¢, whereas on branch roads 2¢ or more may be charged. Freight rates on high-grade ore are generally higher than on low-grade. Values are based upon ore as shipped; dry ton values should not be applied to freight bills because railroad freight has to be paid on the moisture too.

Small shippers seldom can obtain as favorable a rate from the railroads as can the traffic manager for a larger shipper or for large buyers. Partly for this reason and also because small shippers are often short of cash, freight charges are ordinarily paid by the smelter or consumer, the amount being deducted from the returns credited to the mine. Owing to the difficulty of recovering the freight on worthless material shipped by irresponsible or ignorant miners, many buyers are reluctant to accept shipments from sources not previously known to them.

Value of an ore. Assayers and chemists sometimes report not only the metal contents found in an ore but, as a carryover from the days when gold and silver were commonly

reported in dollars, multiply the contents by market prices to indicate the "value" of the ore. Such figures are, of course, ridiculously wrong. The only way to determine the value of an ore to a seller is to calculate it from a smelter schedule with allowances for all smelter deductions and freight charges.

Ore shipped from Butte in the early days yielded no profit to the shipper if it carried less than \$130 worth of Cu (at 19¢) and \$50 in gold and silver. It had to go by bull team and rail all the way to Baltimore; smelter charges were high because of the As content. This is an extreme case but even today the actual value of a high-grade silver ore at the smelter may not be over 70% of its theoretical value; for low-grade ores the percentage may be much less. Low (*58 CMJ 556*) cites several modern examples, of which the following is typical: A copper ore assaying 1.08% Cu, 0.003 oz. Au, and 0.116 oz. Ag yielded 3.2 tons concentrate (dry) assaying 27.63% Cu, 0.06 oz. Au, and 2.45 oz. Ag, representing recoveries of 88.4% Cu, 61.2% Au, and 68.2% Ag. Smelting terms were: Cu assay less 1.3 units, at the dollar equivalent of London copper price (15¢) less 2¢; 98% of gold at \$35 per oz.; 95% of Ag at quotation less 1.5¢; treatment charge, \$5 per ton; freight, \$1 per ton. Returns per ton were: Cu, \$68.46; Au, \$2.06; Ag, \$1.01; less \$6 charges; total, \$65.53, corresponding to \$2.10 per ton of ore. Gross calculated value was \$3.39 per ton. A lead-zinc ore assaying 10.9% Pb, 14.7% Zn, and 2.08 oz. Ag, with a calculated gross value of \$27.99, showed a return of \$12.00 per ton. A pyritic copper ore assaying 3.71% Cu and receiving a credit of 20¢ per ton of ore for pyrite yielded \$9.25 per ton against a gross, based on copper only, of \$11.13. On a 46-ton shipment of high-grade gold-silver ore from Montana Silver Queen Mining Co. (*PC*) to the East Helena smelter the net proceeds were \$14,645.54, while the calculated gross was \$19,081.65.

Iron

Roughly 80 to 85% of United States iron production is from the Lake Superior district and Lake Superior prices tend, therefore, to control country-wide except when a seller's market permits other districts to utilize freight differentials in local areas.

Lake Superior ore is sold at base prices, f.o.b. Lake Erie docks, for 51.5% natural iron assay, with adjustments up or down from the base according to iron contents, and further adjustment in the case of Bessemer ore for phosphorus. Base prices are set each spring, four prices serving as bases for five different ores, comprising three different kinds, *viz.*, Bessemer or low-phosphorus; non-Bessemer or intermediate-phosphorus; and high-phosphorus. Adjustment for iron content is at a price per unit obtained by adding 60¢ to the base price for the class of ore and dividing the sum by 51.5. Thus with a \$5.10 base (per long ton) for 1938, the adjustment price was $(\$5.10 + 0.60)/51.5 = \$0.11068$ per unit. This unit price multiplied by the percentage excess natural-iron assay over 51.5% is added for iron contents above 51.5%, and deducted for deficits down to and including 50%. The deduction from 50% to 49% is 1.5 times the unit; for assays below 49% the deduction per unit is twice the unit adjustment value. Thus for a 47% ore in 1938 the deduction was: 1.5% off at \$0.11068 down to 50%, 1% off at $1.5 \times \$0.11068$ down to 49%, and 2% off at $2 \times \$0.11068$ down to 47%, or a total deduction of $5 \times \$0.11068 = \$0.55$.

Standard phosphorus content for Bessemer ores is 0.045%. Penalties and bonuses are computed on the iron price as above obtained on the basis of 0.8¢ for the first 0.001% difference in P assay from the standard, and this amount increased by 0.05¢ for each further 0.001% departure. Thus a Mesabi Bessemer ore assaying 55% Fe and 0.048% P would have commanded (base price \$5.10, 1938): $\$5.10 + (55 - 51.5) \times \$0.11068 - (\$0.008 + 0.0085 + 0.0090) = \$5.46$ per long ton.

Iron base for southern United States ores is definitely lower than that for Lake Superior because of the self-fluxing character of the impurities ($CaO + SiO_2$).

Average base prices at Lake Superior mines were \$3 to \$3.50 per long ton in the early 1920's and \$5 to \$5.25 in 1938. Southern base averages 50 to 70% of Lake Superior. Northeastern United States concentrates are commonly sold on a unit basis. In general, they command 10 to 20% higher prices than Lake Superior when demand is good and 20 to 30% lower prices when demand is poor.

Minor Metals

Aluminum. Bauxite is the principal ore. For production of metal the Al_2O_3 content should be 50 or 52% Al_2O_3 minimum, less than 7% SiO_2 and 6.5% Fe. Silica premium (<7% SiO_2) and penalty are of the order of 15 to 20¢ per long-ton unit up to and including 13% and 30 to 40¢ per unit for higher contents. Low Fe and Ti (2.5 to 3% max.) are preferred in the manufacture of aluminum chemicals, but SiO_2 may be 15 to 20%; for aluminum abrasives SiO_2 and Fe_2O_3 should be less than 5% each, and TiO_2 less than 4%; for refractories Fe and Ti must be low but SiO_2 may be high. Prices for domestic bauxite during the 1930's ranged from \$6 to \$7.50 per long ton.

Chrome ore. The important characteristics are the Cr_2O_3 content, the Cr : Fe ratio, and the SiO_2, P, and S contents. Typical specifications follow:

		High-grade	Low-grade A	Low-grade B
Cr_2O_3	Min....	45.0%	40.0% *a*	40% *a*
SiO_2	Max....	11.0	13.0	None
P	Max....	0.20	0.50	None
S	Max....	0.50	1.00	None
Cr : Fe	Min....	2.5	2.0	None

a Rejection at 35%; penalties imposed for deficit.

Prices (1942): HIGH-GRADE, base \$40.50 per dry long ton at 45% Cr_2O_3 and Cr : Fe = 2.5; premiums of 90¢ per long-ton unit of Cr_2O_3 above 45.0% and of \$1.50 per ton for each increase of 0.1 in Cr : Fe up to 3.0. LOW-GRADE A, base \$28 at 40% Cr_2O_3 and Cr : Fe = 2.0 with the same premiums as for High-grade; penalty of \$1.40 per long-ton unit deficit in Cr_2O_3 down to 35% Cr_2O_3. LOW-GRADE B, base \$24 at 40% Cr_2O_3 with premium of 60¢ per long-ton unit of Cr_2O_3, and penalty of \$1.20 per long ton for each unit deficit in Cr_2O_3 down to 35%.

Prior to 1939 all U. S. consumption of chrome ore was imported. Prices per long ton c.i.f. Atlantic ports were \$16 for South African Low-grade, and ranged from \$19 for 44% Cr_2O_3 to \$26 for 50%.

Manganese. Domestic ores are of CHEMICAL GRADE (>80% MnO_2); HIGH GRADE, LOW-GRADE A, or LOW-GRADE B according to the following schedule:

		High-grade	Low-grade A	Low-grade B
Mn	Min......	48.0%	44.0%	40.0% *a*
Al_2O_3	Max.....	6.0	10.0	None
Fe	Max.....	7.0	10.0	None
P	Max.....	0.18	0.30	0.50
SiO_2	Max.....	10.0	15.0	None
Zn	Max.....	1.0	1.0	1.0

a 35% min. may be accepted with price penalties.

MANGANIFEROUS ORES are iron ores containing ±10% Mn and ±40% Fe.

Ores are bought on a sliding scale based on a standard specification, *e.g.* (1943).

	Standard (black-oxide ore) *b*	Reject at	Penalties per unit of Mn for each % off standard
Mn............	45.0	Under 40.0%	2¢ per unit *a*
Fe............	7.0	Over 10.0	1¢ per unit
SiO_2...........	10.0	" 15.0	1¢ per unit
Al_2O_3..........	6.0	" 10.0	1¢ per unit
P..............	0.18	" 0.30	1¢ per 0.03%
Zn + Cu + Pb..	1.0	" 1.5	None

a Premium, 1¢ per unit of Mn for each 1% in excess of 45%.
b Concentrate must be nodulized or sintered. Carbonate ore must be calcined.
SIZE SPECIFICATION: None >12-in.; not more than 25% <20-m.

Base price per unit varies with the grade of ore; *e.g.*, in 1943 a base price of \$1 per long-ton unit was quoted for High-grade ore, 80¢ for Low-grade A, and 65¢ for Low-grade B specified as above, with rejection limits in the cases of High-grade and Low-grade A being the specifications for the next lower grade.

Prior to 1939 most of the manganese used in U. S. was imported. Prices per long ton in 1938 were: Chemical grades: 80% min., \$50 c.i.f. U. S. seaport; 85% min., \$60 to \$62 c.i.f. U. S. seaport; domestic, 70 to 72%, \$47 to \$52 f.o.b. mines. Metallurgical grades: 50 to 55% Mn, 45¢ per long-ton unit. Domestic manganiferous ore: 10% Mn, 22¢ per long-ton unit and 5¢ per unit of iron, delivered to furnaces. Manganese metal is sold mostly as 80% ferromanganese; prices per long ton for this alloy have been: 1929, \$105; 1932, \$69.33; 1937, \$97.04; 1938, \$97.40; 1942, \$130.

Tin. Cassiterite concentrate is bought on the basis of an assay adjusted for smelting loss, and subject to a sliding treatment charge that increases with decrease in tin content.

Penalties are imposed for excesses above specified maxima of most of the usual metallic impurities. An abstract of a typical contract (1940) follows:

I. For concentrate containing more than 55% tin, and a maximum of 1% total Sb + As + Bi + Cu + Pb + Zn of which Sb + Pb shall not exceed 0.3%: *Pay* for tin contents less one (long-ton) unit. *Deduct:* BASE TREATMENT CHARGE (60% Sn), $30.40 per long ton, with decrease of $1.20 per unit up to 65% Sn and 60¢ per unit above 65%, or with increase of $1.20 per unit down to 55% Sn. PENALTIES: S, 3% free, 23¢ additional treatment charge for each 0.1%.

II. For concentrate (>55% Sn) with more impurities than I: BASE TREATMENT CHARGE (60% Sn) is $31.60 with adjustments for tin content as in I. PENALTIES: As + Cu + Bi + Zn, 0.5% total free; for excess deduct 45¢ for each 0.1%. Sb + Pb, 0.5% free; excess penalized at 45¢ for each 0.1% up to maximum allowable combined content of 2.25%, of which Sb shall not exceed 0.5% nor Pb 1.75%. S as in I.

III. For concentrate (>55% Sn) containing more than the above allowable percentage of Sb or Pb: BASE TREATMENT CHARGE (60% Sn) is $32.25 with adjustments for tin content as in I. PENALTIES: For combined As + Cu + Bi + Zn, as in II. *Lead:* 1% free; 45¢ per 0.1% excess from 1% to 2%; 70¢ per 0.1% from 2% to 4%; 80¢ per 0.1% in excess of 4%. *Antimony:* 0.5% free; 45¢ for each 0.1% excess from 0.5% to 0.75% (fractions prorated); 70¢ for each 0.1% excess from 0.75% to 1%; excess above 1%, special. S as in I.

IV. For concentrates assaying 35 to 50% Sn: *Pay* for tin content less 1.25% for 55% Sn and increase assay deduction 0.05% for each 1% that tin content falls below 55% (fractions prorated). *Deduct:* BASE TREATMENT CHARGE (55% Sn), $35.00 per long ton. Increase treatment charge 23¢ for each 1% below 55% Sn. Increase treatment charge 1.25¢ for each dollar rise in quoted price of tin above $936 per long ton. PENALTIES: Sb + Pb + Bi + Cu + As, 3% total free; 35¢ for each 0.1% excess up to 5%. If excess exceeds 5%, deduct further 45¢ per 0.1% excess of Sb over 1.2%. As: 45¢ per 0.1% excess over 0.2%. Zn: 12¢ per 0.1% excess over 3% (max. of $7.05 per ton of concentrate). S: 3% free; $2.35 per ton from 3 to 5%; $4.70 per ton from 5 to 10%; $7.05 per ton from 10 to 15%; $9.40 per ton above 15%.

V. For concentrates assaying 18 to 35% Sn: *Pay* for tin content less 1.5%. *Deduct:* BASE TREATMENT CHARGE (25% Sn), $42.25 per long ton; add 60¢ for each 1% below 25% Sn and deduct 30¢ for each 1% increase in assay above 25%. Add 1.25¢ to the treatment charge for each increase of $1 above $936 per long ton in the quoted price of tin. PENALTIES: Sb: not to exceed 2.5%. Cu: 1.5% free; 23¢ per 0.1% excess. Zn: as in IV. As: as in IV. Bi: as As. S: 3% free, 45¢ per 1% excess from 3% to 12%, and 23¢ per 1% excess above 12%.

Tungsten. Ore and concentrates are normally classified into a variety of grades; the following abstract of a broad contract for Bolivian ores is illustrative:

Class A, High-grade wolfram concentrates. Standard quality: WO_3 min. 65%; Sn max. 1.5%; As max. 1.0%; S max. 1.5%; Cu max. 0.8%.

PENALTIES: 45¢ per short ton unit of WO_3, for each 1% WO_3 below 65% down to and including 60%; 9¢ for each further 1% WO_3 below 60% down to and including 55%. Privilege of rejection under this classification if the WO_3 content is less than 55%, or accepting at a mutually agreed allowance. *Tin:* 1.6% free; 3¢ penalty per short-ton unit of WO_3 for each 0.1% tin above 1.5%. *Arsenic:* 1.0% free; 15¢ per short-ton unit of WO_3 from 1% to 1.5%; 20¢ per short-ton unit of WO_3 for 1.5% to 2.0%; $1.00 per short-ton unit of WO_3 for 2% to 3.0%, with a limit on the amount acceptable. *Copper and sulphur:* Ores or concentrates assaying more than 0.8% Cu, or more than 1.5% S and not subject to these rejection options (WO_3 <55%; or As >3.0%; or Cu >1.6%; or S >2.0%), shall be paid for at a discount of $1 from agreed price per short-ton unit of WO_3, subject to the above recited penalties for WO_3, Sn, and As.

BONUSES: If Sn is <1%; As <0.2%; S <0.75%, and WO_3 content 65% or better, pay 10¢ per short-ton unit above agreed price for 65% WO_3, and 10¢ additional for each 1% increase in WO_3 up to 70% WO_3; above 70% as for 70%.

Class B, Low-grade wolframite concentrates containing from 55% WO_3 to 30% WO_3 in the form of wolframite are subject to the same penalties for WO_3, Sn, As, Cu, and S, and to the same rejection options for impurities as for Class A ores and concentrates, and shall pay an additional penalty of $1 per short-ton unit of WO_3 (complex ores of wolfram and tin covered by Class F excepted). Privilege of rejection below 30% WO_3.

Class C, High-grade scheelite concentrates: Standard quality: WO_3 min. 60%; Sn max. 0.5%; As max. 0.5%; S max. 1.0%; Cu max. 0.2%. Base price as for Class A. PENALTIES: 9¢ per short-ton unit of WO_3 for each 1% WO_3 below 60% down to and including 55% (fractions in proportion). Privilege of rejection if the WO_3 content is less than 55%, or acceptance at a mutually agreed allowance. *Tin:* 0.5% free; 3¢ penalty per short-ton unit of WO_3 for each 0.1% tin above 0.5%. *Arsenic:* 0.5% free; from 0.5% to 1% penalty of 15¢ per short-ton unit of WO_3. *Copper and sulphur:* If not subject to these rejections (WO_3 <55%; or Sn >1%; or As >1%; or Cu >0.5%; or S >1.5%) ores and/or concentrates with Cu >0.2% or S >1.0% penalized $1 per ton off the agreed price per short-ton unit of WO_3, subject to the above recited penalties for WO_3, Sn, and As.

BONUSES: If Sn <0.2%, As <0.1%, S <0.75%, and WO_3 60% or more, 10¢ per short-ton unit above agreed price for 60% WO_3; 10¢ additional for each 1% of WO_3 in excess of 60% up to 65%; above 65% as for 65%.

Class D, Low-grade scheelite concentrates and ores containing less than 55% WO_3 and more than 30% WO_3 are subject to the same penalties for WO_3, Sn, As, Cu, and S, and to the same rejection options as Class C ores, plus an additional penalty of $1 per short ton unit of WO_3 (Class F ores excepted).

Buyer may purchase, subject to the above recited penalties, ores and concentrates containing less than 30% WO_3.

Class E, Clean Low-grade scheelite concentrates with negligible Sn, As, and S: \$2.50 short-ton unit of WO_3 off Class C, if they meet the following specifications: $WO_3 > 30\%$; $S < 1\%$; $As < 0.05\%$; $Sn < 0.05\%$.

Class F, Complex tungsten-tin ores and concentrates containing from 20% to 45% WO_3 in the form of scheelite or mixed wolfram and scheelite and 18% to 35% Sn. Price \$3.50 per short-ton unit of WO_3 off Class A. Buyer also pays for 90% of the tin content on the terms paid for Bolivian tin ores (p. 266).

Class G, Low-grade scheelite with content of barium sulphate: \$3 off Class C per unit of WO_3, if the WO_3 content is not less than 30%.

Smelter contracts, and other agreements for sales of ore and concentrates, are subject to specific legal rules of consummation and performance, and should be entered into only under the direction of a competent lawyer, and with the advice of engineers or metallurgists with full knowledge of the technical matters involved. Walker (*Ed. 3 Peele 32–18*) lists points to be covered as follows:

(1) Duration of contract; (2) approximate amount of ore to be delivered; (3) rate at which the ore is to be delivered (if known); (4) point at which delivery is to be made from miner to purchaser; (5) arrangement respecting freight rates; (6) method for weighing the ore; (7) determination of moisture; (8) arrangement for representation of both seller and buyer; (9) manner in which the ore is to be sampled, and sampling paid for; (10) number of final samples to be taken, and disposition of same; (11) assay and analytical methods to be used in determining the ore constituents; (12) settlement of splitting limits; (13) mode of settlement when determinations by seller and buyer are within the splitting limits; (14) arrangement for umpire, if difference exceeds the splitting limits; (15) mode of settlement in case samples are sent to umpire; (16) terms of payment for metals; (17) the effect, if any, which fluctuations in market price shall have on terms of payment; (18) the effect, if any, which the value or composition of the ore shall have on these terms; (19) dates on which metals are to be paid for; (20) statement of payments to be made and penalties to be levied for specific ore constituents; (21) the base on which settlements will be made; (22) amount which will be advanced (if desired) by purchaser to seller, at any time after settlement has been agreed upon and before final payment is made; (23) possible conditions which shall be considered as valid reasons for failure to deliver or receive ore under the contract; (24) arrangements for submitting disputes to arbitrators, instead of to the courts.

SECTION 3

INDUSTRIAL MINERALS

BY

PAUL M. TYLER

Introduction. The solid nonmetallic-mineral industry far exceeds the metallic mineral industry in bulk of material handled annually; the sales value is many times greater; the variety of forms in which the product of the dressing operation is demanded is many fold larger; and the dressing methods are more specific to the crudes, of greater variety, and, while generally of lesser complexity, are, in a few cases, even more complicated. SELLING is almost invariably a matter of individual bargaining between producer and buyer; general specifications are indefinite or lacking completely; and working specifications frequently involve, in addition to specific chemical and physical ranges, requirements as to effects on the senses of the buyer—feel, taste, sight, and even sound and smell—with or without a further test of behavior in some process of manufacture. METHODS OF DRESSING are, therefore, often rule-of-thumb procedures, developed to meet the requirements of a given buyer, inexplicable to a student who does not know the particular specification, and often inexplicable to one who has this knowledge. Generalization as to treatment methods is, under these circumstances, impossible in certain cases, and an attempt thereat would be misleading and harmful. Where it has been deemed possible, flowsheets have been given that will, with normal crudes, yield products that will satisfy general demands and that are capable of minor modification to fit specific demands. In other cases, examples are limited to specific flowsheets; these, in absence of any statement to the contrary, must be taken to represent a specific treatment of a specific crude for a specific market demand, and should be read accordingly.

Prices given in the succeeding articles are for 1938–39 unless otherwise noted.

1. ABRASIVES

Natural abrasive materials may be classified on the basis of the form in which they are used as: (1) MASSIVE, which are shaped directly into grindstones, millstones, pulpstones, whetstones, etc.; and (2) GRANULAR, which are used in the form of loose or cemented

grains. Abrasives act by cutting tiny shavings with each grain; the character and shape of individual grains are, therefore, of paramount importance. Artificial abrasives, especially silicon carbide and electrically fused alumina, are usually more uniform than the natural minerals and have, therefore, gradually displaced the latter for massive grinders, both manufactured and naturally bonded.

The natural abrasives, in order of decreasing hardness, are diamond, corundum and emery, garnet, silica sand and quartz. Highly siliceous materials which occur or are used in powder form as mild abrasives are pumice and pumicite, and the so-called SOFT SILICAS, *e.g.*, diatomite and tripoli. Clay, chalk, and feldspar are used in scouring, cleaning, buffing, and polishing.

Uses. Grinding wheels are used in many industries, but, as above noted, manufactured wheels made mostly from artificial abrasive grains with only minor admixtures of corundum predominate. Emery wheels made from natural abrasive grains are substantially obsolete. In making coated abrasive products, quartz, garnet, and, to a minor extent, emery are still used quite generally. The automobile industry is by far the largest user of both high-grade grinding wheels and abrasive-coated papers or cloths. Today the only demand for grindstones is for diameters greater than 5 ft., for use principally in the making of saws, files, machine-knives, scythes and shears, and cutter-bars for agricultural machinery. Many pulpstones are even larger than the grindstones.

Occurrence. Only occasional sandstone deposits are suitable for grindstones. Apart from requirements as to grain size and bond, such deposits must be thick enough to permit cutting stones of large diameter at right angles to the bed, and the joints must be far enough apart to permit blocks of suitable size to be quarried. Millstones have been produced in various parts of the United States; perhaps the best buhrstones come from France, consisting of fresh-water cellular quartzite or flint of Tertiary age. The United States and England are the largest producers of pulpstones; the domestic output comes chiefly from northern West Virginia. Most grindstones come from Ohio. Carboniferous sandstones appear to be most productive of suitable material for grindstones and pulpstones. Sharpening stones are of wider distribution because they may come from thinner beds; the Arkansas novaculite beds range from a few inches to 15 ft. in thickness, but are badly shattered, so that much waste must be rejected. The well-known Pike (N. H.) scythestone is a mica schist, but fine-grained sandstones and siliceous argillites are also used for sharpening stones. The Belgian razor hone is a damourite slate containing innumerable garnets, and is interbanded with a blue-gray slate so that double-faced stones can be produced.

Production. The United States and Canada are probably the largest sources of natural pulpstones and certain other kinds of naturally bonded grindstones and sharpening stones; but England is an important producer, and similar products are made in other parts of

Table 1. Domestic production of miscellaneous abrasives

Commodity	1925–29 (average)		1930–34 (average)		1937

the world. Artificial nonmetallic abrasives are produced in large quantities in Canada and the United States and are made in France, Norway, Sweden, Germany, and other European countries. Domestic production is given in Table 1.

Granular-abrasive grade designations, for bulk material and for coatings, may be either arbitrary markings, which date back a century, or a bolting-cloth mesh designation which approximates but does not exactly correspond to the Tyler testing-sieve meshes. In modern usage only flint and emery have not yet been brought into mesh designation. Table 2 gives the modern mesh designation and the old garnet, the flint, and the emery scales.

Selling. Sandstone for grinding stones must be of uniform hardness, possess sharp grains of even size, and be free from clay and other soft impurities. Grain size determines the use, but strength of bond has much to do with value, because the stone should crumble in use only enough to prevent glazing the grinding surface. Specifications for all kinds of abrasives are based mainly on performance, and prices depend upon negotiation between buyer and seller.

Sales of domestic pulpstones have averaged around $60 a ton but have fluctuated from less than $50 to more than $80 a ton. In Canada, small stones for 2-ft. wood weigh 2 to 2 1/2 tons and cost (1937) the paper makers $300 each, whereas those for 4-ft. wood, weighing 5.5 to 7 tons each, sold for $1,100.

Treatment. The making of small sharpening stones, oilstones, etc., begins with splitting the stone at the quarry into approximately the desired shape; it is then conveyed to the mill and placed on rubbing beds where it is ground to the desired uniform size. Small pieces of Arkansas novaculite are built up in layers with plaster of Paris into blocks which are sawed with band saws into 2-in. slabs. Ordinary sand is commonly employed for cutting and polishing. Larger stones are usually fabricated by hand, the important point being the extraordinary care that must be taken in handling, not only to avoid chipping the edges but in drying out the quarry sap and preventing frost damage in winter. Large stones are seasoned for as much as 2 years and small ones for 1 year, although the period may be shortened if the stone is first steamed for several hours at about 180° F. in a closed chamber.

Manufactured abrasives are made in electric furnaces. The fused masses are broken with a skull cracker, and eventually the coarse gravel and small lump sizes are screened out and hand sorted as ABRASIVE ORE for shipment to plants where it is further crushed and sized into various types of GRAINS. Fines and other rejects return to the furnace.

Few milling operations require more care than the preparation of high-quality abrasive grains. Whereas the abrasive is worth only about $20 per ton, the grains are worth as much as $100 per ton, but the fines are of small value. Hence the problem is to avoid production of fines as well as to obtain equiaxed grains with chisel-like edges.

Graded crushing and close sizing on screens is the general practice. In a typical plant the crude is crushed to 1/2- to 1/4-in. in a cone or similar crusher; as many as 9 pairs of rolls may be employed in series to reduce the product to 8-m. Certain sizes are finished in a dry pan, but much of the treatment is wet. Virtually all grains are sluiced to rake classifiers, the slime from which is recovered in a thickener and filter, though it has little value. Iron from machines and a small amount of iron-bearing impurities are removed by high-intensity magnets. Final sizing is within exceedingly close limits, as indicated in Table 2. At a typical plant, the products from vibrating screens are re-run twice over double-deck Rotex screens before being spouted to shipping bins.

Concentration of natural abrasives is described under the names of the respective minerals.

2. ASBESTOS

Ores. Asbestos is a commercial term applied to fibrous varieties of several minerals that differ widely in composition and in strength, flexibility, and quality of fiber. CHRYSOTILE, $H_4Mg_3Si_2O_9$, is the fibrous form of serpentine; the bulk of the world production of both long and short fibers is of this variety. Other varieties belong to the amphibole group of minerals; ANTHOPHYLLITE, $(Fe,Mg)SiO_3$,

though brittle and of low tensile strength, is more resistant to acids and heat than chrysotile and is used to some extent for nonspinning purposes; AMOSITE, an iron-rich anthophyllite mined in Africa, has very long fibers, some of which are flexible enough to spin; CROCIDOLITE or BLUE ASBESTOS, $Na,Fe(SiO_3)_2 \cdot FeSiO_3$, occurs in commercial quantities chiefly in Africa and is used like serpentine asbestos for both spinning and nonspinning purposes. Fibrous TREMOLITE, $Ca,Mg_3(SiO_3)_4$; ACTINOLITE, $Ca(Mg,Fe)_3(SiO_3)_4$; and HORNBLENDE, a complex silicate similar in composition to actinolite, may also be classed as asbestos but, except for Italian tremolite, these have little commercial value. MOUNTAIN LEATHER, MOUNTAIN CORK, and MOUNTAIN WOOD are fibrous sheets or masses of naturally felted amphibole but are only mineral curiosities.

Apart from strength and flexibility, the quality of asbestos is measured to some extent by the fineness of fiber and by the amount of processing necessary to reduce it to the fineness desired. SP. GR. of Canadian chrysotile is 2.54 to 2.59, of Arizona fiber (lower in Fe) 2.47, and of the pure mineral probably about 2.2; anthophyllite ranges from 3.1 to 3.2 and crocidolite from 3.2 to 3.3. Notwithstanding its use in heat insulation, asbestos itself does not have low HEAT CONDUCTIVITY. Chrysotile may withstand temperatures of 3,000° F. or more, but is likely to become brittle if heated sufficiently to drive off much water of crystallization; amphiboles contain less water and therefore withstand higher temperatures, except that crocidolite fuses readily on account of its high iron content. Iron impairs the ELECTRICAL RESISTANCE of chrysotile, but amphiboles may have good electrical properties because their iron is combined as silicate.

Uses. The largest use of the longer grades (SPINNING FIBERS) of chrysotile, crocidolite, and (exceptionally) tremolite is in automobile brake linings; asbestos yarns and cloth are also used in gaskets, fireproof curtains and clothing, electrical insulation, conveyor belts for hot materials, and braided and twisted packings. Medium-length fibers are used in shingles and other asbestos-cement products such as pipes and corrugated sheets. Short fibers are felted into paper or millboard or used as binders in 85% magnesia coverings, asphalt paints, cements, stucco, and molded goods. Acid-washed amphibole is used as filtering medium.

Occurrence. There are three types of asbestos deposits, *viz.*, cross-fiber, slip-fiber, and mass-fiber. Most commercial deposits of chrysotile, amosite, and crocidolite are CROSS-FIBER type, the fibers extending across veins from wall to wall, except when interrupted by longitudinal seams. Such veins vary in width from mere streaks to a maximum of about 6 in. In SLIP-FIBER deposits the strands are more or less parallel to the vein walls, occupying shear zones where rock has been subjected to movement and pressure. In MASS-FIBER deposits, confined to anthophyllite, the entire rock is composed of bundles of fibers.

Production. Canada, U.S.S.R., and Africa, in order, are the leading sources of asbestos, but the Canadian output is preponderantly lower-priced short fibers. Domestic (mostly Vermont) production in 1937 was 12,079 short tons, valued at $344,644. World consumption in 1934 was estimated at 300,000 metric tons; Europe used about half, and slightly over one-third was consumed in the United States. In 1937 the United States consumed over 300,000 tons valued well over $10,000,000.

Selling. Asbestos is sold in 100-lb. or 125-lb. bags on a short-ton basis, bags included. Quotations are mostly f.o.b. mines. A short ton bulks 60 to 90 cu. ft., longer fibers being bulkier. Canadian producers sell direct to consumers and also to dealers and agents. See Table 3.

Market requirements are based principally on fiber length, but strength, flexibility, color, chemical composition, and cleanliness are considered. Old practice graded fiber into three main groups: crudes, mill fibers, and shorts. The term CRUDES was applied to fiber of spinning grade, 3/8 in. or longer, which had been hand-cobbed and not passed through the mill. MILL FIBER was spinning fiber that had been prepared mechanically. SHORTS was material too short for spinning. In 1931 Canadian producers agreed upon a uniform classification of mill-produced fibers into nine groups, each group being subdivided into grades. Except for the lowest grades, which are based upon weight per cubic foot, all milled grades are based on tests in a standard machine consisting of a nest of 4 wooden boxes

Table 3. Grades (*b*) and prices of Canadian asbestos

Group	Designation	Fiber length, minimum	Average price per short ton, f.o.b. mill		
			1929	1932	1939
1	Crude No. 1	0.73-in.	$557.38	$400 to 450	$650 to 750
2	Crude No. 2	0.375-in.	331.82	200 to 225	150 to 350
3	Spinning or textile	0-8-6-2	177.30	80 to 125	110 to 200
4	Shingle	0-1.5-9.5-5	75.26	60 to 90	57 to 130
5	Paper	0-0-8-8	38.56	....	40 to 45
6	Waste, stucco, plaster	0-0-6.5-9.5	....	....	21 to 25
7	Refuse or shorts	0-0-1-15 *a*	....	10	12 to 16.50

a Also specified as weighing 35 lb. or less per cu. ft., loose measure.

b Additional to the groups listed, Group 8 is SAND, over 35 but under 75 lb. per cu. ft., and containing a preponderance of rock; Group 9 is GRAVEL AND STONE, mill products weighing 75 lb. and r per cu. ft., loose measure.

comprising 3 metal screens and a bottom tray. Screen apertures, in inches, are 0.5, 0.063, and 0.047 respectively. A 1-lb. sample is placed on the top (coarsest) screen and the nest shaken by an eccentric (25/32-in. throw) at 300 r.p.m. for exactly 2 min. At the end of each test the asbestos that remains in each tray is weighed. Results of this screen test are expressed in ounces. Thus 8–6–1–1 (the best or 3D grade) means 8-oz. on 2-m., 6-oz. on 10-m., 1-oz. on 4-m., and 1-oz. <14-m. Samples for testing usually are taken at the grading machines every 30 min. Owing to unavoidable variations in fiber as it comes from the pit, the quality of mill-run fiber usually is maintained a little higher than its designation.

Prices of Canadian asbestos have fluctuated greatly during the past 20 years. In 1920 Crude No. 1 was selling at more than $3,000 a ton but by 1924 it was down to $365 (compared with $350 in 1913). Shingle stock that sold for $130 in 1920 was down to $45 in 1924.

19. 4 Jumbo mills.
20. 4 as (9).
21. 8 shaking-screen suction tables; see (11).
22. 10 as (16).
23. Jumbo mill comprises a horizontal cylinder, 6 to 8 ft. long, through which runs a horizontal shaft with arms having beveled tips. Speed is moderate. Feed is introduced at the top at one end and is rubbed and ground against the cylinder as it is moved toward the bottom discharge port at the other end by the action of the arms. All wearing parts are replaceable.

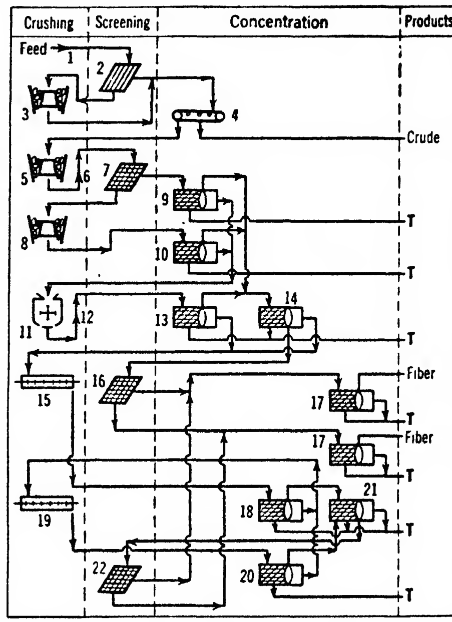

Fig. 1. Typical Canadian asbestos mill.

Treatment (*133 J 102*). Asbestos milling should recover as large a percentage as possible of long fiber even at some sacrifice of recovery of shorter fiber. Flowsheets were formerly quite complicated but practice in Canada, hitherto always the pioneer, is becoming simpler. Essential factors are the fibrous nature and greater tensile strength of fiber compared to serpentine gangue. Crudes and longer fibers are extracted first by a process based on tensile strength before much fiberizing is done on shorter fibers; the latter, after graded crushing, are separated by air suction. The total fiber recovery in Canada in 1929 (*Bul 707 CMB 60*) was 5% of the rock mined and 7.7% of rock milled, but only 1.5% of the asbestos so recovered was crudes and over 90% was short, nonspinning grades. Wet processes for asbestos milling give promise of better recovery of fiber and should eliminate the dust problem, but so far have not been adopted commercially.

Jaw crushers appear preferable for primary breaking, though gyratories are also used. Secondary crushing is done in jaw or gyratory, cone or hammer mill. Tertiary units comprise gyratories, cones, disks (in one case), but are usually hammer mills. Rock is dried at 2- or 2 1/2-in. size in horizontal rotary direct-heat driers. Most mills have at least 25,000 tons storage capacity for dry rock; one can store 150,000 tons so as to avoid all winter mining. Owing to the absorbent nature of the ore, wet storage gives trouble from snow and ice in cold climates. Separation is made by suction through fishtail pipes which are suspended over flowing streams of properly prepared ore. Such pipes may be provided over all crushers and conveyors, as well as over the cleaning devices. Flat, shaking-screen tables with suction pipes are much used for recovery of mill fiber. They separate waste sand (8–

10-, or 12-m. undersize), and stratify rock and fiber with the latter at the top exposed to the action of the ASPIRATORS, which are sheet-metal hoods extending the full width of the table (usually 5 ft.) with a 4-in. opening. Aspirators can be raised or lowered to control the type of fiber picked up. Suction mains are circular (12- to 20-in. diam.); they lead to fiber collectors which operate under 1 1/2- to 2-in. water suction. FLOATS from the top of the collector discharge into one large dust chamber where they precipitate. Collectors, usually vertical cylinders, are 5 to 7 ft. diameter and about the same height; they discharge intermittently by gravity through a canvas trap in the bottom which opens when the weight of accumulated fiber overbalances leather springs.

Fiber thus collected is further cleaned or graded on screens. In modern mills the graders are trommels 3 to 5 ft. diameter and usually 5 ft. long. The first screen may be stationary and equipped with an inner shaft carrying arms and paddles and rotating at 600 to 800 r.p.m. Other trommels rotate but also have light wooden paddles rotating inside them at 180 to 250 r.p.m. to agitate the fiber.

Flowsheet for a typical Canadian mill is given in Fig. 1.

3. BARIUM MINERALS

Ores. Barite, $BaSO_4$, is the principal economic barium mineral. COLOR: white, when pure, but may be gray, yellow, blue, red, brown, or black; LUSTER: vitreous to resinous or pearly; SP. GR.: 4.3 to 4.6; HARDNESS: 2.5 to 3.5; insoluble in water or acids; fuses with difficulty (3 1/2) but usually decrepitates, losing SO_3. Some specimens have fetid odor. Witherite, $BaCO_3$, is not mined extensively except in England; it is almost as heavy as barite, usually somewhat softer, and effervesces with cold dilute HCl.

Uses. Barite is used chiefly in paint, over one-half of domestic consumption being made into lithopone, a white pigment that contains typically 70% precipitated $BaSO_4$ and 30% ZnS. Finely ground barite itself is used in paints; also as filler in various industries, and to a rapidly growing extent as weighting material suspended in rotary drilling muds for high-pressure oil or gas wells. Barite, reduced with C to BaS (BLACK ASH), is the base for most barium chemicals, including precipitated $BaSO_4$ (BLANC FIXE).

Occurrence. Barite occurs abundantly as vein material with lead and zinc ores and also as replacement and cavity fillings in limestone. In the United States it is mined chiefly in residual clays containing particles ranging from sand up to large lumps or masses. Soft or granular barite is preferred to hard, crystalline material, because it is easier to grind. Barite is often associated with flint and calcite and with intergrown hematite, fluorite, or celestite.

Production. World production increased from about 210,000 metric tons in 1913 to 455,000 in 1920 and 900,000 in 1937. Germany, United States, and U.S.S.R. are leading producers, although large tonnages are mined in England, Italy, France, Spain, and other countries. Domestic production, 355,888 short tons valued at $2,225,727 in 1937, comes from three main areas, *viz.*, southern, mid-western, and Pacific. About 80% of the barite produced in the South is shipped to eastern markets, competing with imports; the remainder goes to mid-western markets. The latter, however, are mainly supplied from Missouri, which contributes roughly one-half the domestic output. Georgia is the second producing state, and additional supplies come from Tennessee, Virginia, California, Nevada, and Arizona.

Selling. Ground barite containing as little as 89% $BaSO_4$ may be sold for oil-well drilling, provided the specific gravity is at least 4.2; Fe content is not specified. Ordinarily, however, grinding mills require white barite (or one that readily bleaches white) and specify a minimum of 93 to 95% or even higher content of $BaSO_4$. Lithopone and chemical manufacturers require 95 to 97% minimum $BaSO_4$, 1% maximum Fe_2O_3, and not more than traces of Mn or CaF_2. Strontium is an occasional impurity, but usually is not objected to in small amounts. The glass trade specifies minimum 96% $BaSO_4$, maximum 0.4% Fe_2O_3, and no Mn.

In 1937, the average price of crude barite in Missouri exceeded $7 a short ton for the first time since 1926; the average reported for Georgia mines was about $5.35, in California it was about $6, and in other States prices varied from $3 upward according to freight to consuming centers. Ground barite, in barrels, has been quoted unchanged at $23 a short ton, f.o.b. St. Louis for several years, but average sales f.o.b. mill range from $12 to $25 according to quality (especially color) and locality. Ground witherite, 90% <300-m., has been quoted at $42 to $45 a short ton, f.o.b. Philadelphia, Pa.

Treatment varies with character of ore and scale of mining. In Washington County, Mo. (Weigel, *A TP 201*), much barite (TIFF) is cleaned by hand methods, scraping off adhering clay with hatchets. Roughly picked and dried ore may be rattled in a rocker on a screen with 1/2- to 3/4-in. holes and the undersize rejected or hand-jigged. In larger plants crude ore is dumped into log washers, occasionally after preliminary crushing; head discharge from the logs is screened, followed by hand-picking oversize and jigging undersize. Recent improvements include tabling jig hutch and occasionally classifying log-washer overflow and treating all sand on tables. Flotation, both with soap and with cationic reagents, is readily effected in the laboratory (Sec. 12, Art. 52); two-stage flota-

tion, first with a cationic, would seem best with complex ores. See also *148 A 291* for miscellaneous tests on barite concentration.

Before being finely ground, most barite needs bleaching, usually with hot, dilute H_2SO_4 in lead-lined tanks, NaCl or reducing agents also being added sometimes.

Point Milling & Manufacturing Co. Fig. 2.

Location: Mineral Point, Mo.
Ore: Barite and chert in residual clay.
Capacity: 35 tons cleaned barite per 24 hr.; 500 to 600 tons of feed.
Ratio of concentration: 15 or 20 : 1.
Product: All <300-m.

Legend for Fig. 2:

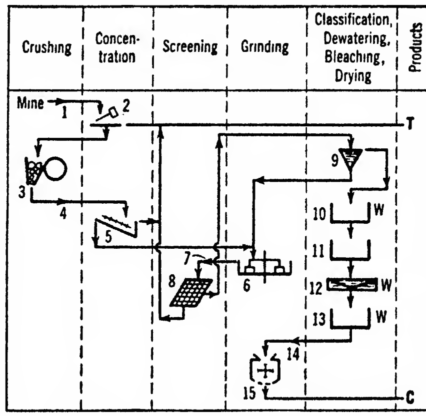
10. 8 @ 7×9-ft. settling tanks.
11. 20 @ 3×9-ft. bleaching tanks made of vitreous tile surrounded by hard lead, which is surrounded by oak staves and iron hoops. Each charge is 2 tons barite with 25% H_2O and a minimum of 240 lb. 66% H_2SO_4. Requires 45 min. to heat nearly to boiling with steam and 6 to 7 hr. minimum to bleach. More acid added if bleach is not complete in 12 hr.



12. 3 @ 10×19-ft. washers, continuous decantation. Leave just enough acid so that iron sulphate gives a slight blue with potassium ferrocyanide.
13. 2 @ 10×2 1/2-ft. settling tanks.
14. 15% moisture; storage tank with agitator; 1 @ 3×8-ft. wrought-iron pipe, 1.5 r.p.m., heated inside with live steam; feed to outside at top from shaking feeder 8 ft. wide at 200 r.p.m.; dried material scraped off on rising side near feed point.
15. Williams pulverizer.

FIG. 2. POINT MILLING & MANUFACTURING CO.

Summary. Rough concentration by cobbing crude, with rejection of waste. Residue crushed and concentrated by log-washing. Concentrate wet-ground, acid washed, dried, and cake disintegrated by hammer-milling.

Thompson-Weinman Co., Fig. 3.

Location: Cartersville, Ga.
Ore: Barite and chert in loose clay and soil.
Capacity: 60 tons white barite per day.

Legend for Fig. 3:

1. Tram line from mine.
2. Grizzly, 7 steel rails 12 ft. long spaced 3 to 4 in.
3. Cobbing.
4. Double-log washer.
5. 1 @ 3×5-ft. trommel, 0.5- to 0.75-in. holes.
6. 1 @ 2×30-ft. picking belt.
7. 1 @ 4-cell Harz jig, 1/8-in. screen.
8. Rejigging.
9. Storage bins, +92% $BaSO_4$.
10. Bucket elevator.
11. Trommel, 1-in. aperture.
12. Picking belt.
13. Jaw crusher, 1-in. set.
14. Log washer.
15. Rolls, set 1/2-in.
16. Log washer.
17. Rotary drier.
18. Raymond mill; 200-m. product.
19. 4 @ 7×7-ft. bleaching tanks, lead- and brick-lined.
20. 10(diam.)×17-ft. washing tanks.
21. Live-steam drum drier.
22. 1 @ 3/8-in. trommel.
23. Picking belt.
24. 1 @ 4-cell Harz jig.

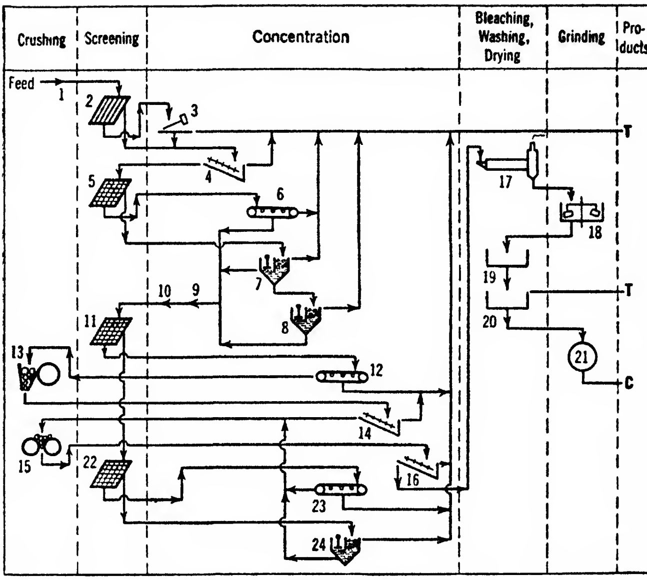


FIG. 3. THOMPSON-WEINMAN CO.

Legend for Fig. 3 on page 7.

Summary. Seven-stage concentration by cobbing, hand-picking, log washing, and jigging at sizes starting at 4-in. and finishing at <3/8-in.; tailing discarded at each stage. Concentrate dried, dry-ground, leached, washed, and again dried.

New Riverside Ochre Co., Fig. 4 (*148 A 277; 143 #10 J 62*).

Location: Cartersville, Ga.
Capacity: 100 t.p.h.
Water: 800 g.p.m. new; 1,700 g.p.m. total.

Legend for Fig. 4:

1. 10 @ 5-cyd. dump trucks.
2. Grizzly, 4-in. spacing; mounted above (3). Waste hand-picked; ore broken through.
3. 1 @ 30-ft. 2-log washer.
4. 1 @ 6-ft. trommel with 2-in. and 1-in. rd. apertures.
5. Rolls.
6. Elevator.
7. Picking belt.
8. Simplex bowl classifier. Sands about 13% $BaSO_4$.
9. 2-deck Hum-mer screen, 5/8-in. and 14-m. apertures.
10. 4 @ 4-cell Harz jigs, 180 @ 1 1/2- to 1-in. s.p.m., 9-in. beds.
11. 2 banks of 4-cell jigs, 260 @ 3/4-in. s.p.m., 9-in. beds.
12. 3-cell jigs, fed from fourth cells of (11).
13. 2 Fahrenwald sizers.
14. 7 shaking tables, triplex Plat-O for the first spigots, single Plat-O with rubber decks and wood riffles for others. 280 r.p.m. Recirculation of middling decreased tailing assay from 10% barite to 7% from feeds ranging from 40 to 70% $BaSO_4$. Concentrate tonnage from 7 tables is 25 to 45 t.p.d., according to feed assay.

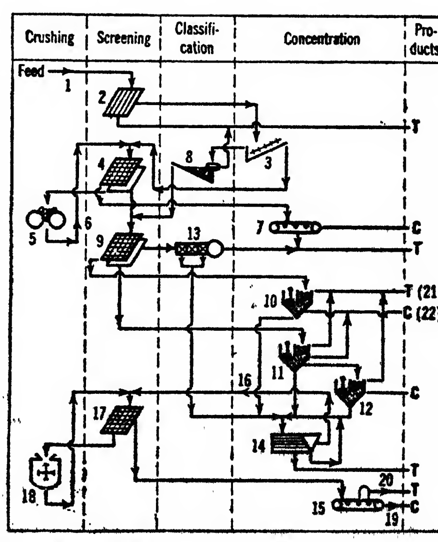

FIG. 4. NEW RIVERSIDE OCHRE C

Legend for Fig. 4—Continued:

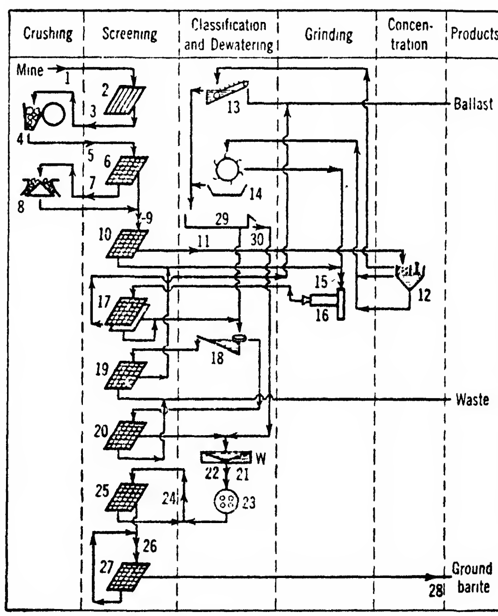
15. 1 @ 20-in. and 1 @ 30-in. Stearns magnetic separators.
16. Stockpile; screw conveyor; 30-in.×30-ft. gas-fired drier. Material ranges from 1 to 6% Fe.
17. 1 @ 12-m. Hum-mer screen.
18. Hammer mill.
19. 0.7% Fe irrespective of Fe content of feed (16).
20. Average assays: 45% Fe and 25% $BaSO_4$.
21. Screened on 3-m.; oversize used for company roads; undersize sold for asphalt sand.
22. Sent to magnetic plant when desired for glass ore.

Power: About 200 hp. consumed.
Ratio of concentration: About 8 : 1.
Products: Low-grade, 92% $BaSO_4$, 5% Fe (for drilling mud); lithopone grade, >96% $BaSO_4$, <1.0% Fe; glass ore, 98% $BaSO_4$, <0.3% Fe; tailing, 8 to 10% $BaSO_4$.

Summary. Four-stage concentration beginning with roughing by hand-picking at 4-in., first finished concentrate by hand-picking at 2~1-in., jigging at 1-in. to 14-m., and tabling of classified <14-m. sands.

National Lead Co., El Portal plant, Fig. 5 (*142 #1 J 33*).

Location: El Portal, Calif.
Crude: Barite and witherite with quartz and calcite.
Product: 300-m. ground barite (little witherite), principally for drilling mud.



Legend for Fig. 5:

1. Mine cars.
2. Grizzly, 12-in. aperture; oversize sledged through.
3. Bin; plate feeder.
4. 1 @ 14×38-in. Blake crusher, 2-in. open setting.
5. Belt conveyor; bin; 3,000-ft. tramway; 1/2-ton buckets (24 t.p.h.); terminal bin; rotary feeder.
6. Inclined fixed screen, 1-in. aperture.
7. A parallel flow from another mine, comprising an 8×16-in. jaw crusher, 2-in. open setting, joins here.
8. 1 @ 2-ft. standard cone crusher, 3/4-in. set.
9. Conveyor.
10. Trommel, 7/8-in. holes.
11. Bins, 3 belt feeders.
12. 2 @ 1-compartment and 1 @ 2-compartment Harz jigs in parallel.
13. Drag classifier.
14. Sand wheel.
15. Mill bin; rotary feeder.
16. 1 @ 8-ft.×36-in. conical mill, light load of <1 1/4-in. punchings. Pulp density maintained at 3.4 floats waste out rapidly.
17. 1 compound trunnion trommel, 3/16-in. and 30-m. screens, on mill (16).
18. 1 @ 7(diam.)×4×21 2/3-ft. bowl-rake classifier.
19. Trommel, 50-m.
20. 14-m. screen.
21. 9×30-ft. thickener; heated to about 80° F. to increase settling rate.
22. 2 diaphragm pumps; preheating and mixing tank.
23. 2 @ 5×15-ft. rotary steam-heated film driers.
24. Screw conveyor; bucket elevator.
25. 1 @ 10-m. Rotex screen.
26. Screw conveyor; 3 @ 500-ton storage tanks; screw conveyor; bucket elevator; hopper with disk feeder; screw conveyor.
27. 1 as (25).
28. Bucket elevator; screw conveyor; packer bin and packer (100-lb. sacks); hand trucks; R.R. cars.
29. Settling trough.
30. 200-m. chip screen.

Fig. 5. National Lead Co., El Portal plant.

Summary. Concentration by jigging at <7/8-in. and by sink-float separation in the grinding mill (Fig. 5, item 16).

4. BENTONITE

Properties. Bentonites are fine-grained, plastic clays, composed principally of montmorillonite or beidellite. TYPE 1, of which the Black Hills bentonites are characteristic, swells enormously when wetted; TYPE 2, sometimes called SUB-BENTONITES, swells no more than ordinary clays. High-grade bentonite will absorb 5 times its weight of water and swell to 15 times its dry bulk. With 18 to 20 parts of water it forms a thin sol, and in concentrations as low as 1 : 5,000 most bentonites remain dispersed for months.

Uses. Type 2 bentonites are used chiefly in oil-well drilling muds, or for making acid-treated bleaching earth. In 1939 it was found that they were preferable to Type 1 for certain kinds of foundry work. Type 1 is used chiefly in foundry and molding sands, to a lesser extent for oil-well drilling, in still smaller quantities in a variety of industries as a suspending, spreading, thickening, adhesive, or paste-forming agent; and to some extent as a detergent and as a lubricant. See also *TP 609 USBM* for a list of minor uses; also a description of evaluation tests.

Occurrence. The Black Hills deposits worked are 2 to 4 ft. thick, close to surface; the bentonite contains 25 to 45% moisture. Other bentonite and sub-bentonite deposits are typically thin-bedded; some spread over wide areas, others are lenses of no great extent. Underground mining is handicapped by the sticky and sometimes almost fluid nature of the water-soaked bentonite strata.

Production in 1925 was 2,500 short tons; in 1937, 194,768 tons, valued at $1,500,758, was produced in the United States, of which slightly over half was Type 1 and came chiefly from South Dakota and Wyoming. Except for a small amount in British Columbia, there is no commercial production of Type 1 outside of the United States. Type 2 is produced principally in Texas, Mississippi, California, Arizona, Oklahoma, and Utah; deposits in Arkansas, Kentucky, Tennessee, and other states have been investigated but not worked extensively. Italy began to exploit deposits of white bentonite in 1938.

Selling. Powdered bentonite, in bags, f.o.b. Black Hills plants, sold at $30 a short ton and upward from 1923 to 1927, later declined to $11 to $13, and the price for air-floated f.o.b. Chicago in 1938 was $25 a ton. Dried, coarsely crushed bentonite was quoted at $7 to $8 a ton, in bulk, or $10 in bags, f.o.b. Wyoming, in the same year. The usual commercial grade is powdered, 90 to 95% <200-m. (dry sieve) and is packed in 100-lb. bags. Some uses require 99% <300-m., which costs up to $40 or $50 a ton. Sub-bentonites are mostly sold crude, at prices ranging from $2 to $5 or more f.o.b. mines, according to location.

Treatment. Bentonite is ordinarily dug by hand and hauled by trucks to processing plants, often 10 to 15 mi. distant. It is dried in rotary driers to 8% moisture; temperature is held to about 480° F., as the gel-forming properties are injured by temperatures above 750° F. The dried material is quite friable. It is crushed to about 3/8-in., usually in rolls driven at different speeds to cause tearing; special cutting boxes are also used. Thereafter it is ground, preferably by attrition, using ball mills, slug mills, rod mills, or roller mills. COST of crushing and drying alone is reported as high as $3 per ton.

5. BITUMENS (SOLID, NATIVE)

Occurrence and properties. The principal minerals are: (1) native asphaltites such as gilsonite, grahamite, and glance pitch (MANJAK), distinguished by their hardness (about 2 Mohs) and relatively high fusing point (230° to 600° F.); (2) native asphaltic pyrobitumens, such as wurtzilite (H = 2 to 3), distinguished by infusibility and comparative insolubility in carbon disulphide (CS_2); (3) mineral waxes, such as ozokerite, distinguished by high content of crystallizable paraffins; it is related to MONTAN WAX, which is a product of extraction of certain German lignites; (4) native asphalts, containing varying amounts of inorganic matter, distinguished by comparative absence of crystallizable paraffins; lake asphalt (SP. GR. 1.4, HARDNESS 1 to 2, SOFTENING POINT 183° to 189° F.) contains 54 to 56% bitumen, 38.5% colloidal clay and silica, and 4% combined H_2O; MALTHAS is an asphaltic liquid that exudes from crevices of rocks in oil regions. Albertite is a dense, lustrous bitumen; and (5) bituminous rock, which is sandstone or limestone containing 2 to 12% or more of asphalt. Bituminous sands are also reported.

Uses. The two best grades of gilsonite, SELECT and JET ASPHALTUM, are used principally in the manufacture of varnishes and japans, printing and rotogravure inks. Ordinary or STANDARD GILSONITE, also known as SECONDS, is used for storage-battery boxes and other molded articles, brake linings, tile and mastic, sealing compounds, insulation, and wood stain. Weathered gilsonite is used in roofing felts and rubber compounds. Wurtzilite, commercially ELATERITE, is used in paints and for protective coatings, electric insulation, and in rubber. It is insoluble and refractory and must be converted into KAPAK (wurtzilite asphalt) by prolonged heating under pressure before use. Ozokerite is used principally for wax candles, petrolatum, electrical insulation, wax ornaments, and waterproofing. After refining it is known as CERESIN. Lake asphalt is used extensively for paving, roofing insulation, and paints, but petroleum asphalt, *i.e.*, the bituminous residues from distillation of petroleum, is a strong competitor. Bituminous rock is crushed, pulverized, and fluxed with petroleum asphalt for paving.

Material with more than about 10% asphalt may yield a surplus for use in floor tiles, plastic planks, roofing felt, etc.

Production of domestic bitumens, both native and manufactured, is given in Table 4. Bituminous rock asphalt has been produced mainly in Kentucky and Texas, to a less extent in Oklahoma, Alabama, Utah, and California; other native bitumens only in Utah. Production of Trinidad asphalt averaged 222,000 short tons a year from 1920 to 1929. Venezuelan production was 77,042 tons in 1924, declining to 7,421 in 1932, when it ceased. Both deposits are owned by an American company. Imports into the United States rose from 113,417 long tons in 1920 to 141,052 tons ($1,138,898) in 1927, then declined to 20,000 to 25,000 tons in 1937–38. Natural asphalt and related bitumens have also been produced in Italy and Germany, in minor amounts possibly also in France, U.S.S.R., Spain, Japan, and Turkey. Bituminous rocks occur in many countries. In 1938, imports of Cuban grahamite rose to 3,826 short tons valued at $65,344.

Table 4. Production (tons sales) of bitumens in the United States
(*Minerals Yearbook*)

	1920		1929		1937	
Gilsonite	56,204	$548,776	54,987	$1,235,920	38,038	$ 973,007
Wurtzilite	*a*	*a*	200	30,000	133	10,621
Ozokerite	....	....	290	133,400	....	....
Grahamite	9,940*a*	133,998*a*	....	....	....	....
Bituminous rock	132,353	531,134	748,550	4,071,173	447,213	2,035,410
Total native bitumens	198,497	$ 1,213,908	804,027	$ 5,470,493	485,384	$ 3,018,038
Manufactured asphalt:						
Domestic petroleum	700,496	11,985,457	1,650,387	18,227,795	2,476,454	25,478,565
Foreign petroleum	1,045,779	14,272,862	2,238,255	25,661,639	1,555,499	17,515,872

a Wurtzilite included with grahamite in 1920.

Selling. Since 1925 the average value of all bitumens, f.o.b. mine shipping point, has been a little above $20 a ton ($22.77 in 1938). Wurtzilite sold in 1931 for $90 a ton, dropped to $79 in 1935–37, and to $77.90 in 1938. Ozokerite is higher-priced. The average value of imported grahamite in 1938 was about $17 a ton, f.o.b. Cuban shipping point.

The average value of petroleum asphalt at refineries in 1938 was $9.24 a short ton, compared with $15.04 in 1920. The average reported value of the imports of lake asphalt from Trinidad was $10.50 in 1938, compared with $8.86 in 1920. Variable proportions of crude and refined asphalt may alter these comparisons, but the inference is that Trinidad costs have risen while refinery prices have come down. Solid and semisolid asphalt (less than 200 penetration), made from domestic petroleum and used for paving only, averaged $14.75 in 1920 compared with $8.33 in 1938.

Treatment. Utah gilsonite is simply hand sorted and bagged for shipment. Crude wurtzilite, however, is refluxed under pressure at 500° to 580° F., which results in reduction of the material to a plastic mass; this upon further heating becomes KAPAK. Cuban grahamite is hand picked and sacked either in crude form or after steam refining. Trinidad asphalt is an emulsion of bitumen, water, mineral and vegetable matter; it is dehydrated locally in steam-heated open tanks or sent to the United States for refining.

6. BORATES

Occurrence and properties. The principal minerals are natural borax ($Na_2B_4O_7 \cdot 10H_2O$), kernite or rasorite ($Na_2B_4O_7 \cdot 4H_2O$), colemanite ($Ca_2B_6O_{11} \cdot 5H_2O$), ulexite ($Na_2 \cdot Ca_2B_{10}O_{18} \cdot 16H_2O$), sassolite ($B_2O_3 \cdot 3H_2O$), boracite ($5MgO \cdot MgCl_2 \cdot 7B_2O_3$), and priceite, a lime borate. The Kramer district, Kern County, Calif., dominates the market; here borates mixed with some clay occur over a wide area in tabular beds, 85 to 100 ft. thick. Searles Lake brines yield borax as a joint product with potash and other salines.

Uses. Few substances have so diversified applications (see Schaller: *IMR*); the principal outlet is in porcelain enameling which, with glassmaking, accounts for nearly 75% of domestic consumption. It is also used extensively in cleaning preparations for homes and laundries; in pharmaceutical preparations, paper, textiles, and tanning. Boric acid is used in eye-washes, for hair-waving, and in other ways.

Production. California produces upward of 90 to 95% of the world's annual output of borates. Domestic production, in terms of refined borax, was 358,898 short tons valued at $7,232,897 in 1937, of which 40% was exported. In 1920, world output barely exceeded 150,000 short tons, of which the United States furnished 120,320 tons, Chile 17,445, and Turkey 13,986, with minor amounts from other South American countries. Italian production is between 5,000 and 6,000 tons. Minor amounts of borates are produced in nearly every continent.

Selling. Refined borax, formerly priced at $800 a ton, has recently been valued at about $20 a ton, f.o.b. California plants. The New York quotation in 1938 was $46 to $51 a ton, delivered, in bags. Minor quantities of crude minerals are marketed occasionally, but prices depend upon private negotiation. Shipments of granular borax are made chiefly in bulk, or in bags, but barrels, kegs, and other containers may be used.

Treatment. At KRAMER, Calif., borax and kernite are mined together because the granular borax particles assist in grinding the fibrous kernite. The mixed borates, after being ground, are calcined to remove water and then most of the clay is removed by screening and air separation before shipment to Wilmington, Calif., for further refining by chemical methods. The borates are dissolved in hot water and, after separating insoluble impurities, borax is recovered from the leach liquor by crystallization. At the WILMINGTON refinery the cleaned ore is leached, leaving clay and most of the impurities in a sludge; the solution is filtered, cooled to speed up separation of crystals, and the crystals are centrifuged out, dried, and screened. Boric acid is obtained by acid treatment of borax. At SEARLES LAKE, Calif., the production of various salts from mixed brine is essentially one of evaporation followed by fractional crystallization, borax being one of the last to separate. In Italy, the recovery of B_2O_3 is a step in a complex process whereby volcanic steam is utilized first as a source of power and then is made to yield not only boric acid but CO_2 and NH_3 as well (*32 CM 520*).

When colemanite was a leading source of borates it was concentrated mechanically before refining, by calcining and decrepitating mine-run product, crushed through 3/4-in., in rotary kilns at 1,470° F., screening on 24-m. shaking screens, and removing clay from the colemanite-rich undersize by pneumatic tables or air classifiers. Oversize, comprising ulexite and gangue (shale, limestone, etc.), was ground to 25-m. and wet-concentrated by Harz jigs and tables, since the calcined ulexite is only slightly soluble in cold water and is somewhat lighter than the gangue.

For floatability of borax minerals see Sec. 12, Art. 52.

7. BRUCITE

Occurrence. Brucite, $Mg(OH)_2$, contains 69.1% MgO compared with 47.6% in raw magnesite. Hardness is 2.5; sp. gr. 2.4. It usually occurs associated with magnesite in serpentine and dolomite.

Uses. The only important outlet is for furnace refractories, largely to increase slag resistance of dead-burned dolomite. Small quantities have been used in petroleum refining and for making Mg compounds. Some massive material is carved into ornaments. It is a potential source of metallic Mg.

Production. Some thousands of tons of brucite is produced annually from the deposit near Luning, Nev., but production figures are not available.

Selling. No published quotations are available; the Nevada mine is operated by the principal consumer.

Treatment. THE CANADIAN BUREAU OF MINES (*43 CIMM 481*) reported tests on a brucitic limestone containing 20 to 35% brucite as disseminated granules; it was found possible to recover the brucite by calcining, hydrating the calcined material to convert the lime to hydrate, leaving the calcined brucite in its original granular form, and separating it from the lime by screening and washing, thus saving both products.

8. CHALK AND WHITING

Properties and uses. True chalk is soft, friable, fine-grained, light-colored limestone, consisting essentially of calcareous shells of minute organisms; WHITING is the finely divided product obtained by grinding crude chalk or ordinary limestone or marble; PRECIPITATED CHALK or calcium carbonate is chemically prepared, often a by-product, but certain precipitated grades are simply finely ground and water-floated, *i.e.*, precipitated from suspension, not solution. Great quantities of chemically precipitated $CaCO_3$ are thrown away in the manufacture of basic magnesium carbonate from dolomite. Recently the paper industry has found it worth-while to reclaim the $CaCO_3$ formed in soda-pulp making for use as a paper filler, partly displacing china clay.

Whiting is consumed chiefly in the paint industry (about 50%), rubber manufacture, and in putty; further quantities are used as filler in oilcloth, linoleum, window shades, and cigarette papers; as a pigment or extender in white ink, white shoe dressings, picture-frame moldings, dolls, and dyes; in tooth pastes, medicines, fireworks, explosives, and wire insulation; and as a neutralizing agent in fermentation and general chemical processes.

In paints and calcimine, the physical requirements are more important than the chemical; fineness, strength and workability are important also to the rubber trade; the putty trade is interested mainly in plasticity, oil absorption, and oil retention, as well as fineness. Color is a factor in most uses. Even rubber makers, however, specify nearly pure $CaCO_3$. Alkalinity is important in dentifrices, toilet, and most chemical uses; the pH value of all whiting is greater than 7.8, but for precipitated whiting it runs up to 8.3 or even 9.6, which is sufficient to cause saponification in putty. The best test

of whiting for putty is a simulative service test of several months. Ceramic whiting should contain under 0.25% Fe_2O_3, 2.0% SiO_2, and 0.1% SO_3; it is further graded according to $MgCO_3$ content. Good bulk density or fluffiness is characteristic of good chalk, but probably the property that best distinguishes true chalk from ordinary limestone is its amorphous character.

Occurrence. Crudes must be substantially pure. The European chalk-cliff crudes contain flint balls which are readily separable by cobbing. The United States crudes, found chiefly in the Middle-Central and Southern States, are mostly mixed with too much clay or sand to be classed as commercial.

Production. Formerly virtually all whiting used in the United States was ground in seaboard mills using crude chalk imported from England, France, Belgium, and Denmark. Before 1914, such imports, chiefly from England, ranged from 100,000 to 150,000 tons or more annually, and as much as 2,000 tons of ground whiting or PARIS WHITE was also imported. The wider use of precipitated chalk and of limestone flour as a whiting substitute was a World War development; subsequently the importation of true chalk has remained stationary or declined, averaging less than 100,000 tons a year. Production of precipitated whiting, chiefly for the paper industry, has increased greatly, possibly to as much as 75,000 or 100,000 tons per year. Large increases have occurred in the use of whiting substitute, sales of which were 125,000 tons in 1929 and 194,080 tons in 1937; the gain in this product is largely due to its use in rubber mixtures, but also to displacement of imported chalk.

Selling. English or French crude chalk is valued at about $1.25 per long ton, f.o.b. mines. The four grades of chalk whiting are (1) COMMERCIAL, (2) GILDERS, (3) EXTRA GILDERS, and (4) PARIS WHITE. Even the cheapest grade was quoted around 1¢ per lb. prior to 1932, but by 1934 it had dropped below 0.6¢ Extra gilders and Paris white may be priced up to 1 1/2 times as much as commercial grade. Dry-ground commercial limestone (99.75% <300-m.) during the 1930's has remained nominally quoted at 1/2¢, less $2 freight allowed, or about $8 per ton, f.o.b. mills. Wet-ground limestone costs a little more; the putty grind sells for about 3/4¢ per lb. For chemically precipitated chalk for pharmaceutical trade, there are five grades worth about 3¢ per lb.; most important is the light or medium-light grade used in toothpastes.

Treatment. Chalk whiting made by the older English method is water-ground in edge-runner or stone-drag mills, after flint pebbles are removed by hand, and then classified in a series of tanks. The products in each of the four final tanks are further settled, and the sludges remaining after siphoning off the clear water are filter-pressed, dried, pulverized, sieved, and bagged. Modern equipment for wet-grinding includes rolls, Mueller grinders, and pebble mills; bowl or cone classifiers and hydro-bowls are used for classification; and thickeners, continuous filters, and rotary driers for dewatering. The cheaper dry process employs impact pulverizers, roller mills, ball mills, or air-swept tube mills, with air separators. Silex- or porcelain-lined mills and flint pebbles are used for grinding ceramic grades. Much of the whiting made from marble or limestone rock is wet-ground in pebble mills, which yield a better product than dry-grinding; the sediment in settling tanks, containing 50% H_2O, may be sprayed on steam-heated drum driers. A 4×10-ft. drum, revolving at 2 1/2 r.p.m. and using 75-lb. steam, will dry 8 to 12 tons in 24 hours. Regrinding to break up cake is done in impact pulverizers. Precipitated whiting is made by blowing CO_2 into milk of lime or as a by-product, especially in paper mills where soda ash is causticized with CaO.

Hessle Whiting plant (*44 #5 RP 53*), at Hull, Yorkshire, England, grinds 3 t.p.h. of pure, white chalk, arriving with 12 to 25% moisture. Head-size quarry rock is broken to <1/2-in. in a hammer mill; dried to 0.5 to 1% moisture in a direct oil-fired rotary drier at 240° F. outlet temperature; and ground in a standard 3-roll high-side Raymond mill discharging to a cyclone collector.

9. CLAY

Occurrence and properties. Commercial clays are mixtures which contain not only aluminum silicates but quartz, mica, and usually other minerals. Important commercial distinction is made between primary or residual clays and secondary or transported clays. Most of the best of pottery kaolins are primary; many are iron-stained. Transported clays are mostly water-borne, but some are glacial and others wind-formed deposits (LOESS). Clays laid down in large lakes, broad estuaries, or bays are likely to be well-sorted. Owing to the precipitating action of salt water on colloids, marine clays are the finest-grained but usually are so contaminated with minute quartz and other mineral grains that they are less valuable than relatively poorly sorted river and lake clays. Refractory clays are commonly found immediately below coal seams (Carboniferous).

Kaolinite ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) is the essential constituent of kaolins, ball clays, refractory underclays, and certain flint clays, but it is not present in all clays; it is more refractory than other clay minerals such as beidellite, montmorillonite, halloysite, and hydromica (sericite). Dickite and nacrite are identical with kaolinite in composition but differ somewhat in optical properties. Excepting pigments, bleaching clays, bentonite, and certain other highly plastic clays, almost no clay will sell for more than about $3 per ton unless it is white or will fire white. A rough test for whiteness is to rub the powder on high-quality calendered paper such as is used in better-class magazines. Particle size, plasticity, and firing behavior also affect the value. Texture is essentially the same thing as particle size; nothing >160-m. can be considered clay. Whiteness is greatly improved by fine particle size

(<2-μ). Binding power is closely related to plasticity; so-called LEAN CLAYS lack this property, either because they contain sand or lack some specific characteristic ingredient or structure. Sedimentary clays generally are more colloidal than domestic primary clays and tend to have more "retention" (in paper mats), a property that has grown to be highly important as increasing proportions of clay are used in book and other fine papers.

Uses. About 60% of domestic sales of kaolin are for paper-making; this industry also uses part of the imports of English clay; more than 10% is used in rubber; about 10% in ceramics (though pottery makers buy mostly foreign clays); almost 10% in refractories; nearly 5% for making white Portland cement; and over 5% in various industries, chiefly as a filler. BALL CLAYS, which are highly plastic, and strong clays (often containing lignite) are used in white earthenware, porcelain, tile, and other products as a binder for china clay and to impart plasticity. FIRE CLAYS, most of which are infusible below about 3,000° F., are used mainly for refractories but find employment in other products as well. For making common brick and other heavy-clay products, a great variety of relatively low grade clays are used. Considerable amounts of special adsorptive clays are used as decolorants in refining lubricating oils.

Production. From 10 to 15 million tons of clay in the United States and huge tonnages elsewhere are dug and used annually by the producers of brick, tile, sewer-pipe, and other heavy-clay products. Only high-grade clays are marketed in substantial quantities in the raw state. Except for a moderate business in fire clays, international trade in clays is confined to the exports of high-grade china and ball clays from Cornwall and Devon. The output of English clays rose to a peak of 965,206 long tons in 1913, but this record was not equaled again until 1937 because the United States, which formerly took more than one-third of the English exports, developed a large kaolin industry in Georgia, South Carolina, and Florida, and eventually came to supply most of its ball-clay needs from Kentucky and Tennessee. Pennsylvania also produces kaolin and is by far the largest producer of fire clay; Ohio, Missouri, Kentucky, and California are other large producers of fire clays, and these are produced in smaller quantities in a score of other states. Ordinary and common-brick clays are produced in almost every locality where demand for the products justifies the existence of a plant. See Table 5.

Table 5. Salient statistics of the merchant-clay industry of the United States, excluding bentonite and fuller's earth, in short tons (*MY*)

	1909–13	1925–29	1930–34	1937
Domestic clay sold by producers:				
Kaolin, china clay	132,114	453,618	431,932	732,282
Ball clay	63,371	116,127	70,299	121,470
Fire clay	1,771,667	2,898,576	1,487,364	2,785,344
Miscellaneous clays	414,814	575,708	305,973	403,522
Total domestic:				
Quantity	2,381,966	4,044,029	2,295,568	4,042,618
Value	$3,736,487	$13,918,171	$7,533,910	$14,207,306
Imports:				
Kaolin, china clay	261,266	339,014	140,888	146,523
Common blue and Gross-Almerode	19,763	12,130	11,306	38,549
Other clay	33,259	61,048	24,713	17,946
Total Imports:				
Quantity	314,288	412,192	176,907	203,018
Value	$1,873,096	$3,715,725	$1,528,039	$1,920,891

Selling. Notwithstanding substantial improvement in quality, the average prices of domestic kaolin declined from above $8.50 a short ton in the late 1920's to $5.75 in 1932, rising to $7.31 in 1937. In 1937, however, a leading producer quoted paper clays at $7 to $30, the latter price representing a specially processed coating clay. The harsh kaolins used only for refractories ranged in value from $1 to $4 a short ton, f.o.b. Georgia mines; paper-filler clays from $6.50 to $10; and paint or linoleum clays, from $6.50 to $9. South Carolina paper clay sold mostly around $7 or $7.25, rubber clays slightly higher. Typical quotations for English clays delivered at United States Atlantic ports ranged from $14 to $25 for paper clays and $18 to $25 for pottery clays, including freight (say $3.50) and duty ($2.23) in 1937. Ball clays range upward from $6.75 a ton. The long-term trend for fire clay has been definitely upward, the 1937 average being $2.71 *vs.* $1.39 in 1913. Shales and surface clays for common brick, although rarely sold, are worth around 5¢ per ton in the ground, if well-situated; prices for common brick vary according to locality and market conditions, but the general range is between $10 and $20 per M. First-quality firebrick costs about $50 per M. Roughly 3 tons of clay is needed per M brick.

Treatment. COMMON CLAYS, such as are used for heavy-clay products, and most fire clays, will not stand the cost of beneficiation beyond the limits of selective mining, thorough mixing (and blending, if necessary), plus, possibly, crushing or screening out pebbles. Shales are crushed, pulverized, screened, and either PUGGED (wet-ground or TEMPERED)

for soft- or stiff-mud products, or they are dry-ground and dampened for semi-dry press products. BRICKS may be molded by hand, but mechanical methods are almost universal. Soft-mud bricks are wiped or pressed wet into individual molds. In the stiff-mud process, the clay paste is forced through a die as a ribbon which can be cut transversely into brick sizes, usually by a wire. Green brick rough-shaped by either process may be re-pressed to exact dimensions, usually after partial drying. Dry-pressing is used mainly for floor and wall tile but has been adopted by many firebrick makers and is gaining ground in other branches of the ceramic industry. Although brick may be dried in the open air, modern clay-products plants have artificial driers, usually of the car-tunnel type. Various kilns may be employed for burning products; common brick may even be piled up to form their own kiln (SCOVE KILN), arched spaces being left at the bottom for the fire and the outer courses being laid close and sealed with mud to retain heat. For soft common brick, the minimum firing temperature is close to 900° C., the average for ordinary brick being perhaps 1,050°; for vitrified brick the temperature is higher and heating must be continued longer. Fire-clay brick are burned at 1,250 to 1,400° C., and a few special products require up to 1,640° C.

KAOLINS, being usually sandy, are commonly beneficiated. Dry processes seemed to be displacing wet methods for a while, and are still indicated where only a little moderately coarse grit needs to be removed. Wet methods, owing to the cost of removing large quantities of water, cost more but are more flexible, yield finer grades of product, and are more selective. With froth flotation, even the clay minerals themselves can be separated from one another (Sec. 12, Art. 53).

FILLER CLAY and many RUBBER CLAYS are satisfactorily prepared by dry hammer-mill pulverization followed by air separation. Blue dye may be added to bleach paper clays, and low-temperature calcination under oxidizing conditions, followed by chlorination, has been used to improve whiteness without destroying the colloidal properties sufficiently to diminish retention.

In a SOUTH CAROLINA plant (*30 #4 PQ 69*) rubber clays are air-dried to 15% moisture, passed through a slugger-roll crusher, and reduced to 1/2 to 2 1/2% moisture in rotary driers (requiring about 40 lb. coal per ton of clay). Raymond 5-roller mills with Whizzer separators grind the product to 99.9% <200-m. This plant is so arranged that the whiter clays can be wet-processed for paper and ceramic use, by crushing such clay in a duplicate slugger roll, blunging in a pug mill, and sending slurry to Hum-mer screens, which reject all >200-m. Clay for certain uses is bleached chemically on its way to a thickener, the sludge from which is filter-pressed. Filter-cake contains 25% moisture and is pugged before going to the drier, where moisture is reduced to 3%.

Soft kaolins that disintegrate rapidly in water may be dispersed in log washers, beaters, or other simple blunging devices, and the grit settled out in troughs and tanks, with or without supplementary screening. Water suspensions or SLIP carry only 3 to 8% clay and can be thickened to not more than about 25 or 30% solids. Pressure filters require up to 150 lb. per sq. in. on the pumps and the cake often carries 30% moisture. Before drying, filter-cake may be pugged or passed through an auger machine to form hollow cylinders or other shapes that can be dried quickly on steam racks or in car-tunnel or rotary driers. Long-established practice in CORNWALL depends upon hydraulicking to obtain dispersion. The clay-sand stream there is run through sand pits or boxes before being pumped out of the pits, which are often quite deep; the remainder of the coarse sand is dropped in a series of riffled troughs or sand drags before flowing into the MICA TROUGHS, which are 1 to 2 ft. wide, about 9 in. deep, slope about 1 in. in 50 ft., and are arranged in batteries so that the slurry flows slowly for a distance of 250 ft. or more. At SPRUCE PINE, N. C., hydraulically mined slurry was raised to surface in bucket elevators, sand wheels were used to eliminate pebbles and coarse sand ahead of the mica troughs, but hydraulicking was being abandoned in 1937–38 because it failed to provide a uniform flow of material. The modern plants at HARRIS CLAY CO. are shown in Figs. 6 and 8. Developments in clay washing include tube-mill disintegration, using pebbles or rubber-covered balls or rods; wet-process micropulverizers (*A TP 744*); use of electrolytes with careful pH control for dispersion and flocculation; bowl classifiers and hydroseparators; centrifuges, cataphoresis (electric deflocculation and precipitation); and hot-spray-chamber drying. Sodium silicate seems to be more efficient than Na_2CO_3 for deflocculating and dispersing clay; subsequent coagulation with alum is possible only when water is not reclaimed, as even a small amount of residual alum reduces greatly the benefit derived from the use of deflocculants. In GEORGIA, coating clays are treated in solid-bowl continuous centrifuges with or without an electrophoretic attachment. Iron may be reduced by running the slip through the Frantz Ferrofilter or by chemical treatment with SO_2 and zinc.

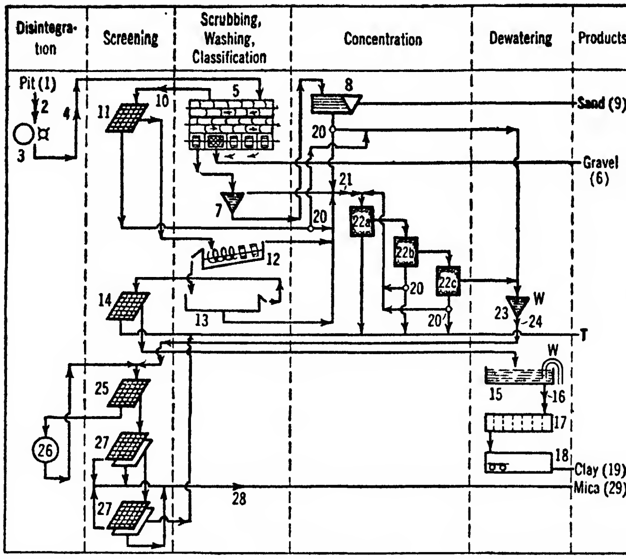
FIG. 7. CAROLINA CHINA CLAY CO.

Summary. Separation of clay from sand and mica by disintegration in water and sedimentation; separation of sand from mica by crushing the sand and sizing and jigging.

Kaolin, Inc., Fig. 8 (*45 #9 RP 40; 142 #7 J 56*).
Location: Spruce Pine, N. C.
Ore: High-grade potash feldspar, flint, kaolin, and muscovite mica. Mica ranges from 1/2-in. to 325-m. See Table 6.
Capacity: 400 t.p.d. of crude; 1 t.p.h. of mica, max.; kaolin, 60 tons per 24 hr.
Products: Concrete aggregate, flint and hard feldspar; quartz sand; kaolin; mica (see Table 6).



Legend for Fig. 8:

1. Drag scraper in pit; hopper.
2. 1 @ 18-in. × 450-ft. conveyor.
3. Bartlett & Snow roll disintegrator, 25-hp. motor; knives on smaller roll; one roll only driven; run dry.

2 parallel sections, each as follows:

4. 1 @ 16-in. inclined belt conveyor; 1 @ 40-ton steel bin.
5. Special blunger, 7 ft. deep, 18 ft. long, 10 ft. wide at feed end, 7 1/2 ft. wide at sand-discharge end; divided longitudinally into 3 compartments by vertical partitions and the third compartment divided transversely into 5 compartments. Compartments 1 and 2 carry logs with 30-in. curved knife blades mounted radially; shafts are adjustable vertically. Compartment 3 carries a through shaft, parallel to the logs, on which are mounted sand wheels in the first three and the fifth subcompartments, and a trommel in the fourth, having an outside spiral. Feed enters at one corner of compartment 1; water with a dispersing agent enters at the diagonally opposite corner of the machine into subcompartment 3–5. Clay overflows midway of the side of compartment 1. The trommel in subcompartment 3–4 discharges >4-m. through the side of this compartment; <4-m. is pushed into subcompartment 3–5 by the trommel spiral and after washing in 3–5 is discharged by the sand wheel therein.
6. Stockpiled; part sold locally for concrete aggregate.
7. Deister cone-type hydraulic classifier, 6-m. split.
8. 1 Plat-O table.
9. 1 @ 16-in. belt conveyor; storage bin, part sold, balance wasted.
10. <20-m. mica, <50-m. sand.
11. 3 @ 3×6-ft. single-deck Niagara screens, 50-m. or 70-m. stainless-steel cloth.
12. Sand reel comprising a 5×25-ft. tank with sloping bottom and a spiral and 3 sand wheels on the shaft; the final wheel lifts out sand.
13. 4 @ 4 1/2(deep) × 7 × 30-ft. sand boxes in parallel, fed alternately for 5 to 7 hr. or until sand and mica begin to overflow.

Streams joined

14. 5 @ 5-ft. rotary screens in parallel, 200-m. aperture; oversize is wood chip with a little mica.
15. 8 @ 57,000-gal. wooden settling and decantation tanks; flocculant added; discharged at 30% solids.
16. 3 @ 27,000-gal. fir mixing tanks.
17. 12 @ 24×24-in. Crossley filter presses; cake, 70% solids.
18. Tunnel drier, 170° F., 22 hr.; dried cake, 5% moisture.
19. 1,250-ton covered stockpile; tunnel conveyor to car-loading bin; shipments run about 7% moisture.
20. Alternative.
21. 4 feeds run separately; 7,500-gal. tanks provided for thickening and storage of settlings during runs of table concentrate and screen oversize.
22. 1 @ 8-cell 42×42-in. M-S subaeration machine for feed from (12) and (8); 1 @ 6-cell No. 18 Special Denver Sub-A machine for feed from (13) and (11). *a* = 4 cells of M-S and 3 of Denver;

Fig. 8. Kaolin, Inc.

Legend for Fig. 8—Continued:

b = 2 cells, each machine; c = 2 cells of M-S and 1 of Denver. REAGENTS reported: DuPont 243, Armour amines, Armour F (soap), pine oil, sodium silicate, soda ash.

23. Dewatering tank; sand, 70% moisture.

24. Fletcher batch centrifuge to 30% moisture; storage bin with screen feeder; 54-in.×30-ft. Louisville steam-tube (260° F.) rotary drier, product 1% max. moisture; Rotoclone dust collector on drier shaft.

25. 1 vibrating screen (scalping), 10- or 20-m.

26. Prater pulverizer.

27. 1 @ 2 1/2×7-ft. and 1 @ 2 1/2×10-ft. 2-deck Rotex screens.

28. Oversizes separately to Howe flour-mill bagger.

29. Usual sizes are Nos. 40, 60, 80, and 160; 16 to 20 lb. per cu. ft.

Summary. Blunging, washing, and screening to separate kaolin from mica and granular siliceous minerals; screening and tabling to separate coarse and sandy granular minerals from mica; flotation to separate finer mica and quartz.

10. CORUNDUM AND EMERY

Occurrence and properties. Corundum (Al_2O_3) ranks among natural substances next to diamonds in hardness, but the step from diamond to corundum is far greater than that comprised in the remaining eight steps in the Mohs' scale. HARDNESS (= 9) varies slightly, sapphire being hardest and other varieties grading down to emery which is 8. SP. GR. ranges from 4.1 to 3.9. Fine clear crystals of corundum are gemstones: ruby (red), sapphire (blue), oriental emerald (green), and topaz (yellow). They occur in placers and in deeply weathered residuals. Common corundum is opaque and is used chiefly as an abrasive. It occurs as BLOCK or massive corundum and as SAND or small irregular grains. Magnetite, apatite, biotite, garnet, and tourmaline are common accessory minerals. Gem corundum has a conchoidal fracture, but the common variety has a prominent basal parting and cleaves easily, producing smooth flat surfaces.

EMERY is an intimate mixture of granular corundum and magnetite, with some hematite; it is usually reddish black. Greek (Naxos) and Turkish emery ordinarily contain 60 to 70% or more Al_2O_3 and only a fraction of a per cent. of MgO; Spanish emery is mixed spinel (pleonaste hercynite) and magnetite with variable quantities of corundum, or even none at all. It is usually a heavy, fine-grained aggregate with the corundum appearing as dark gray crystals; it often shows alteration to mica. FELDSPATHIC EMERY is a similar mixture containing 30 to 50% plagioclase instead of spinel. HARDNESS is 2.7 to 4.3. It is usually magnetic and breaks with a moderately regular fracture. Domestic emery deposits, mostly spinel, are in mica schists, pegmatites, or complexes of igneous rocks, but the best Naxos and Turkish emery occurs as pockets and lenticular masses in crystalline limestones and residual red clays.

Uses. About 70% of the corundum sold in the United States, which is the world's largest consumer, is used in grinding wheels (usually admixed with artificial abrasives); about 30% is used for lens grinding, polishing rock specimens and gems, etc. Corundum was used formerly instead of bauxite concentrate for a specially fused alumina abrasive. Imported emery is used in grinding wheels, emery paper and cloth, and for glass polishing and beveling. Domestic emery, which is softer, is used mainly in pastes and compositions.

Production. Most natural corundum comes from South Africa, which produced a maximum of 5,996 short tons in 1926. U.S.S.R. is an important producer, although

Russian statistics may include emery. India, Southern Rhodesia, and Namaqualand have reported spasmodic exports, generally small in recent years. Domestic production since 1929 has been confined to a small output from the Peekskill region, N. Y., amounting in 1937 to 320 short tons valued at $2,780.

Emery comes principally from Greece and Turkey, with increasing amounts from U.S.S.R. and very small amounts from the United States and Germany. In 1926 Greece produced 27,000 long tons out of a world total of perhaps 38,000 tons. Recently the world total has been less than 30,000 tons, of which Greece has produced 8,000 to 12,000 tons and Turkey and the U.S.S.R. each about 8,000 tons.

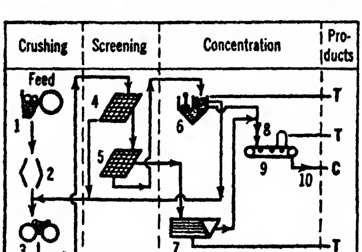
Selling. The principal barrier to large use of natural abrasives is the difficulty of maintaining uniform quality, in the face of the uniform character of the artificial product. South African corundum has a small domestic market because of special suitability for certain uses, comparative cheapness, and efficient marketing combined with government certification of grading of all export shipments. GRADE A is over 92% Al_2O_3; B, 90 to 92; C, 85 to 90; and D is under 82% Al_2O_3. Each grade of crystal corundum is further subdivided according to size as COARSE (>1/2-in.), MEDIUM (1/2~1/4-in.), FINE (1/4~1/8-in.), MIXED or C/4 GRADE (>1/8 in., guaranteed plus 85% Al_2O_3). Titanium, more than any other impurity, seems to harden and toughen corundum grains so that the grains in grinding wheels become dull, instead of fracturing to new sharp cutting edges. Grains finer than 1/8-in., sometimes called CONCENTRATES, sell at lower prices than crystal. Average prices of BOULDER corundum in South Africa are usually below $20 per short ton; crystals cost about $38 per ton locally and $60 and upward delivered in the United States.

Greek and Turkish emery are shipped in lumps ranging up to 25 lb.; the material is crushed and graded by 5 mills in the United States into 12 sizes of COARSE-GRAINED (6- to 46-m.), 12 sizes of FINE-GRAINED (54- to 220-m.), and 4 FLOUR grades from F to FFFF; finer dust is prepared for optical work. Emery containing higher percentages of corundum is desired for grinding wheels; a more friable product is preferable for polishing and for pastes. Recent quotations have been $10 per short ton for first-grade American crude ore, f.o.b. New York, or $16 delivered to grinders; and $30 to $40 a ton (350-lb. bags) for Turkish and Naxos, delivered to grinders. American grain has been steady at 4 1/2¢ and foreign grain at 6 to 7¢ per lb., f.o.b. grinders. In 1936 and 1937, Naxos emery was priced as follows, ex-warehouse at Syra: first-quality, large lumps (over 640 gm.), £4 12s.; small lumps (80 to 640 gm.), £4 6s.; second-quality, £4; and fragments (chips), £3 13s., all per metric ton.

Treatment. South African corundum, from scattered alluvial deposits yielding as little as 5% workable crystal, is concentrated by shoveling against an inclined stationary screen (@ 3/4-in. aperture), shaking oversize in hand-screens to cause the corundum crystals to collect at the center, whence they are picked out by hand. Undersize goes to rockers with 1/8-in. sieve, undersize of which is rejected and oversize is scrubbed in a hand-worked rotary pan. Mixed lumps are tumbled dry by hand in a half-filled barrel until adhering waste is knocked off, then screened. Final grading is performed at a central buying depot. More drastic cleaning is obtained quickly in a commercial plant by passing ore (>1/8-in.) through a 10-ft.×18-in. steel pipe in which beater blades revolve at high speed.

Mechanical milling was attempted in South Africa some years ago to obtain marketable concentrate from low-grade boulder corundum and other reef deposits. Marundite and micaceous plumasites failed to yield suitable concentrate owing to difficulty of separating the flaky minerals, biotite and margarite. Feldspar-plumasites, though rarely containing over 40% corundum, were more amenable to treatment. One of the early mills made the mistake of crushing with stamps, thereby sacrificing the yield of more salable coarse and intermediate grain sizes. The flowsheet of a mill which was built in 1930 and closed down the following year is shown in Fig. 9.

South African Corundum Co., Fig. 9 (*Bul 6 Geol Surv. So. Af. 50*).
Location: Bandolier Kop, North Transvaal.



Legend for Fig. 9:

1. Jaw crusher, 2 1/2-in. set.
2. Disk crusher, 3/4-in. set.

8. Hot-plate drier.
9. Magnetic separator.
10. <80-m. dust and fines removed by wet classification or dry-screening.

FIG. 9. SOUTH AFRICAN CORUNDUM CO.

Summary. Crushing to 8-m., jigging 8~16-m., tabling <16-m., and treating dry concentrates on magnetic separator.

Canadian mills (*Bul 675 CMB*) used jigs and tables to produce 55% concentrates from 10.5% ore; were dried and separated magnetically, then reconcentrated on Wilfley tables or air jigs and

given final magnetic treatment and resizing on vibrating screens before bagging. Concentrate ran 90 to 95% Al_2O_3; total costs of production were about $40 a ton. Tailing from the old CRAIGMONT mill (*Ed. 1, p. 112*) ran 4 to 6% corundum; it was treated later in a new mill, regrinding though 14-m., classifying closely, and wet-tabling to get rough concentrate for further treatment in the old grading mill.

Greek and Turkish emery is hand-sorted and sledged to size, sometimes assisted by heating and quenching in water. In the United States it is broken in jaw crushers, a series of rolls to $^3/_{16}$-in., and ball mills in series. In dry mills mica is separated by dropping the ball-mill product down a chute against an uprush of air; other mills wash the crude grain in hardwood mullers of Chilean-mill type, the overflow from which is passed through a series of long settling troughs. Trough settlings are shoveled out, dried, and screened into 3 or 4 grades of flour; the finest flour grades are made by settling the overflow from the troughs in tanks. Washed grain is sized in troughlike shaking screens into about 30 different sizes. (See Art. 1.)

11. CRYOLITE

Occurrence and properties. Cryolite (Kryolith) ($3NaF \cdot AlF_3$) is a snow white to icelike mineral easily cleavable into approximately cubical fragments. HARDNESS, 2.5; SP. GR., 2.95 to 3.0. It fuses at 950° C. and is insoluble in water. It occurs commercially only at Ivigtut, Greenland, associated with pegmatite minerals and various sulphides. Reserves were estimated at more than 1,250,000 tons in 1938.

Uses. Cryolite is used chiefly to form the bath for aluminum reduction furnaces; also in glass and ceramic industries (opaque glass, glazes, abrasive wheel binder, and insulators), and as an insecticide for dusting plants.

Production. The mine is owned by the Danish Government. Production ranged in the 1920's between 20,000 and 30,000 tons and in 1937 reached the record of about 50,000 tons, of which about 17,000 tons was shipped to the United States.

Selling. The Pennsylvania Salt Co. of Philadelphia and the Cryolite Mining Co. of Copenhagen handle all the raw output, the average declared value of the imports into the United States ranging all the way from $21 per long ton in 1915 to $86.25 in 1929. In 1937 crude from Greenland was valued nominally at $56.50 per long ton; refined cryolite, $160 a long ton; synthetic cryolite, $180 a long ton. Cryolite is free of duty. Three grades of refined cryolite are marketed: KRYOLITH, 98% pure, contains a maximum of 1.5% SiO_2, 0.25% Fe_2O_3, with CaO seldom over 0.1%; KRYOFLUX and KRYOCIDE contain 93 to 94% cryolite and not more than 0.75% Fe_2O_3; and the latter is more finely ground.

Treatment. Nonfluoride minerals are sorted out at the mine. The sorted ore is then screened, hand-picked, crushed through $^1/_4$-in., and passed under high-intensity magnets to remove siderite and some of the pyrite. Jigs and tables are employed to remove galena, pyrite, silica, and other minerals, concentrate is recleaned on Wilfley tables and magnets, then ground in porcelain-lined mills with porcelain balls, and air-separated to yield products of which 99% is <150-m. and 90% <300-m.

Synthetic cryolite is made from acid fluorspar, Na_2CO_3 and bauxite, the CaF_2 being first converted into HF. It competes with the natural product not only in aluminum reduction but also in enamels and insecticides.

12. DIAMOND

Properties. Diamonds are crystalline carbon; HARDNESS, 10; GEM VARIETIES have extremely high REFRACTIVE INDEX (2.42) and dispersion or "fire"; they are cold to the touch, and transparent to X-rays, whereas paste imitations are not. LUSTER is greasy and rather dull before cutting. CARBONS or CARBONADOS are opaque, imperfectly crystalline, and lack cleavage; they are much tougher than the more crystalline gemstones; have a dull, earthy LUSTER, and SP. GR. ranging from 3.15 to 3.29, compared with 3.50 to 3.52 for the best gem diamonds. Poorly crystallized diamonds of dark color, often fibrous in structure, are called BORTZ (BORT or BOART); they are intermediate in character between gem diamond and carbonados, although the name is also applied to gem-diamond crystals of inferior quality and to chips and fragments from cutting for gems. BALLAS is a globular mass of radiating crystals, exceedingly hard and tough, but exceedingly scarce.

Uses. Only transparent stones free from visible flaws are valued as gems. Pure white, or "first-water" stones, and those with good green, blue, or red tints, are most valuable. Blue-white stones also are highly esteemed, but a tinge of undesirable color, such as yellow or brown, greatly impairs the value. Carbonados were formerly used chiefly to point bits for diamond-drilling but are now increasingly used for dressing abrasive wheels and for pointing, cutting and shaping tools, while bortz and even gemstones are used in diamond-drilling, the bit being studded with 50 or 60 small stones instead of 4 to 8 larger carbons. Small gem and carbon chips and powdered bort, bonded with metal, are used in circular saws, drill bits, and stone-dressing tools, and for cutting and polishing gemstones. Larger stones are used for wire-drawing dies, glass cutters, and pivots for delicate apparatus.

Occurrence. Carbonados are found almost exclusively in surface gravels in the highlands of Bahia, Brazil. Gemstones have been produced principally from alluvial deposits, but in South Africa they are also found in an altered basic igneous rock locally called

kimberlite or BLUE GROUND. Elsewhere they have been found in peridotite, but usually these stones have been too small or sparse for economic working.

Production. World production of diamonds increased from about 4,063,000 carats in 1933 to about 9,003,000 carats (1,988 tons) in 1937. The average value, f.o.b. mines, has decreased from $9.38 per carat in 1912 to $4.83 per carat in 1937. Only about one-fourth of the annual output is colorless gem material, and scarcely 5% of the total is fine, large ROUGH weighing 2 carats or more. Since the loss in cutting is about 55%, only 150,000 carats of good cut stones or, say, 100,000 fine large diamonds are added to the world's stock in a normal year. Recently the proportion of high-grade stones has been even less. About one-half the annual output is suitable only for abrasives.

About two-thirds of the quantity and three-fourths of the value of the output have usually come from the British Empire and over 95% from the African continent, but in 1937, owing to the extraordinary increase in output of the Belgian Congo, only 37% by weight and 68% of the value was from the British Empire. Brazil and British Guiana are leading non-African sources at present. British India used to be the leading source and has furnished many of the world's most famous diamonds.

The exports of Brazilian carbonados run from 10,000 to 30,000 carats yearly.

The United States is the largest consumer both of gem diamonds and abrasive diamonds.

Selling. Sizes range from microscopic grains to fist-size; the Cullinan diamond weighed over 1 1/8 pounds (3,106 carats), commercial stones average 1/4 to 1/6 carat or about 1/10-in. in diameter. Price per carat varies with size as well as with quality. The proportion of large stones is greater in India and South America than in Africa and the average quality is perhaps better. Bort of good quality retails for about $7.50 a carat. Carbonado runs from $35 to $80 a carat; around 1930 it rose to $175 a carat, which speeded substitution. Ballas usually costs about twice as much as carbonados. Averages are not particularly informative as to gemstones, however, since dealers bid on specified parcels, on the basis of the value of the cut stones that may be obtained from them. In 1938, a well-cut fine diamond, weighing one carat, was worth about $650 retail, a one-half to three-quarter carat stone of like quality was worth $350 to $400, and a 2-carat stone might bring as much as $1,500 to $2,000. Even in the United States, the average retail sale is less than one carat, persons in the middle-income group being the principal buyers.

Treatment. Many diamonds are produced by natives using gold pans or bateas, breaking up cemented gravel with sledges, washing out mud and fines, and hand-picking the washed gravel on a flat surface. Larger alluvial-diamond operations comprise mechanical treatment (see Fig. 10), consisting essentially of stage crushing, the final stages in corrugated spring rolls with light spring pressures; roughing out upward of 95% of the feed in diamond pans; jigging closely sized grades to a bulk of about 0.1% of original feed; reconcentrating jig concentrate on grease tables; and, after removal of grease, removing magnetic sand by magnetic separation, and picking over the remaining material, grain by grain, on a stationary sorting table. Extreme care is taken throughout to guard against theft.

Blue ground weathers and crumbles enough in 4 to 18 months to release the diamonds, and this practice was formerly followed, but it has been found that the crushing scheme outlined in the preceding paragraph breaks so few diamonds that crushing is much more economical than the expensive spreading, periodic plowing, guarding, and re-collection of the feed involved in BLUE-GROUND FARMING or weathering.

De Beers Consolidated Mines, Ltd. Fig. 10 (*2 # 12 MQE 449*).
Location: Kimberly, Union of So. Africa.

Legend for Fig. 10:

1. Headframe hoppers; shaking feeders; belt conveyors with magnetic head pulleys.

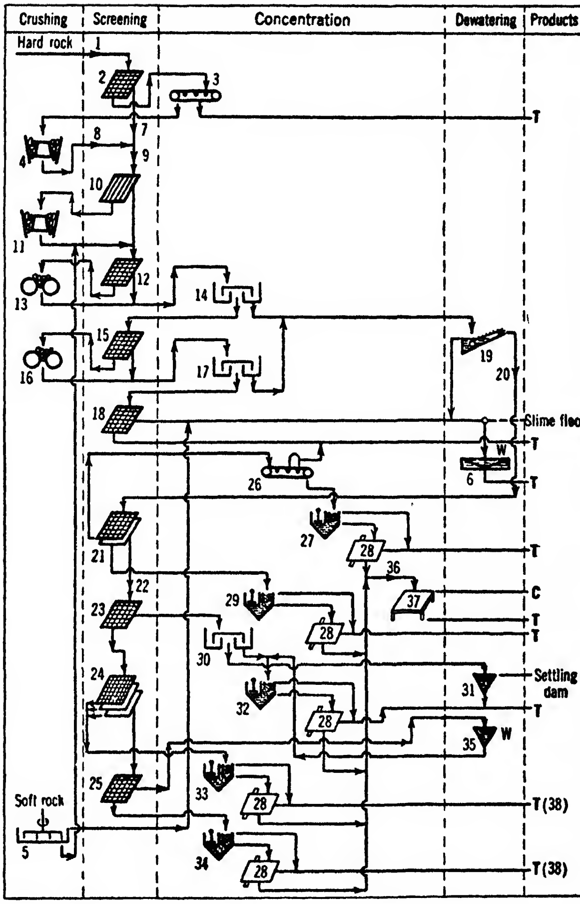
28. Grease table. (See Sec. 12, Art. 17.)
29. De Beers jig, 5/8~3/8-in. feed.
30. Safety pan, 8-ft. diam.
31. Sand cone.
32. 2 Richards jigs, <1/16-in. feed.



Legend for Fig. 10—Continued:

33. 3 De Beers jigs in parallel: 1 on 1/8~3/16-in.; 1 on 3/16~1/4-in.; 1 on 1/4~3/8-in.

34. 2 De Beers jigs in parallel on 1/8~1/16-in. feed.

35. 1 as (31).

36. <1/8-in. diamonds, gravel, and grease *via* grease boiler, stationary magnets (magnetic *via* ball mill) to sorting table; other sizes separately *via* grease boiler, caustic, and hydrofluoric acid washes, directly to sorting table. The remaining concentrate is principally diamond and zircon.

37. Hand-sorting table; sizes sorted separately.

38. These sizes kept separate for sale.

FIG. 10. DE BEERS CONSOLIDATED MINES.

Summary. Graded crushing in gyratories and rolls from run-of-mine to 1-in., with intervening hand-sorting of waste and separation of fines by screening and washing. Rough concentration by pan washing at <1-in. and scavenging at <3/4-in. Pan concentrate sized into 7 sizes from 1-in. to fine sand and jigged, rejecting tailing and sending concentrate to grease tables, the concentrate of which is cleaned and hand sorted.

13. DIATOMITE

Properties. Diatomite or kieselguhr consists of the siliceous remains of diatoms. Pure varieties are friable, with APPARENT HARDNESS 1 to 1.5, although the hardness of the microscopic particles is 4 to 6. SP. GR. is 1.9 to 2.35, but apparent density of dry blocks is 0.4 to 0.6 and of dry powder 0.08 to 0.25 (5 to 16 lb. per cu. ft.).

Uses, in approximate order of importance, are: filter aid, especially in sugar refining; insulation; fillers; admixture in concrete; and, in smaller amounts, in metal polishes, scouring and cleansing soaps and compounds, dentifrices, and nail polishes; as an abrasive; as a source of silica in the manufacture of water glass; in ultramarine and sundry other chemical products. For further details see *IMR 243*

Production. At least 23 countries have produced diatomite commercially and undeveloped deposits occur elsewhere. World production (1937) was over 175,000 tons, of which the United States produced considerably more than half and Denmark about one-fourth. Most of the remainder came from Germany, U.S.S.R., Algeria, and Japan; and fairly large quantities from North Ireland, Spain, Australia, Canada, Italy, and Hungary.

Selling. Diatomite products include cut blocks or brick, crushed aggregate, and powder. Diatomite brick, with clay or other binders, is made from suitably crushed and graded aggregate. Specifications for diatomite products vary greatly because of wide diversity of uses. For specialized filtration and filler uses, definite chemical and particle-size specifications may be required. For polishes, color as well as size and absence of grit may be important. Low-priced crude diatomite may be graded only on its bulk density and moisture content. Frequent practice is to submit standard samples in lieu of specifications. Diatomite products, other than crude, are rarely shipped in bulk. Packaging costs are high; even the powders may be injured in shipping. Crude diatomite is worth as little as $5 or less a ton, but admixture, insulation, and filtration grades are priced from $10 to $40 at the mines, highly purified or selected qualities as high as $100. Insulating bricks range in price from $40 to $80 per M.

Treatment. At western United States deposits the crude earth from open quarries or cuts is field-dried to some extent before being taken to the mill. Coarse waste is removed on grizzlies before primary crushing, and sand, trash, and tramp iron are removed from the crushed product in mechanical traps ahead of the secondary mills (mostly swing-hammer type) and air classifiers. The product may be the natural powder or a calcine or chemically treated product, which is redispersed or even reclassified by special mills or blowers, before bagging. In Germany water classification is practiced. The Bureau of Mines has tested separation of clay and grit from impure earth by both wet and dry methods. Bog and pond deposits in the eastern United States are dredged, the peaty mixture filter-pressed; the cakes are air-dried on racks and then calcined to remove organic matter as well as moisture.

At the FLOATSTONE Co., Wilmington, Calif. (*19 #4 PQ 83*), raw earth (75 t.p.d.) is crushed in toothed rolls, ground in a tube mill swept with hot air, in closed circuit with an air classifier, the <200-m. product of which is divided by a second classifier into <200-m. and <350-m. grades. Calcining is done, if desired, at 1,900° to 2,400° F., according to subsequent use.

Purification of diatomite experimentally by dispersion of clay with sodium silicate and removal by decantation and by flotation with low-molecular weight amines (*e.g.* amyl) is reported (*148 A 356*).

14. DOLOMITE

Occurrence and properties. Dolomite may constitute mountain ranges; many calcitic limestones have become dolomitized by the action of magnesium-bearing solutions. Dolomite, $Ca,Mg(CO_3)_2$, is a distinct mineral, but grades into magnesium limestones when the $MgCO_3$ content drops much below 45%. Dolomite and ankerite, $CaCO_3(Mg,Fe)CO_3$, are distinguished from calcite ($CaCO_3$) in that they do not effervesce freely with *dilute* HCl. SP. GR. is 2.85, slightly heavier than calcite; HARDNESS, 3.5 to 4.

Production and uses. Statistics are included under limestone; uses overlap. Many statuary marbles are dolomitic. The dolomitic limes of Ohio are often preferred for brick mortars and finishing-coat plasters, being stronger, more plastic, and having more sand-carrying capacity than high-calcium lime. Vienna lime, used in buffing compounds, is made from stone analyzing 43% $MgCO_3$. Magnesium content is also advantageous in sulphite-paper making, agriculture, and occasionally for glass making and metallurgical fluxing. "Technical carbonate" of approximate formula, $4MgCO_3 \cdot Mg(OH)_2 \cdot 5H_2O$, is made from dolomite by the Pattinson process, or a modification thereof, for use in 85%-magnesia molded insulation and also in pharmacy, rubber, paint, glass, printing inks, cosmetics, free-running table salt, toothpaste, etc. Epsom salt may be made from dolomite, often with CO_2 as a joint product. The most important distinctive use of dolomite is in refractories. Raw dolomite in rice size is used for patching furnaces; dead-burned dolomite, for steel-furnace bottoms. The largest tonnages are used in concrete aggregate and as flux stone for smelting; considerable tonnages are used for stone sand, for agricultural stone, and for dusts for various purposes.

Selling. Dolomite, at best, is a low-priced commodity. Consumers, as a rule, either own quarries or have established contractual relations which guarantee supplies. Prices approximate those of limestone.

Treatment is by calcining (see Art. 24). $MgCO_3$ lowers calcining temperature. In burning high-calcium lime the temperature may be carried to 2,200° F., but temperatures above 1,560° F. may over-burn high-magnesium lime, the resulting product being dense, discolored, and over-difficult to slake. Dolomite for refractories is dead-burned at

2,730° F., usually in rotary kilns, often after admixture with controlled amounts of other materials containing Fe, SiO_2, and/or additional Mg to stabilize the CaO. Flux stone, aggregate, and stone for burning are produced by crushing to suitable limiting sizes and then sizing to obtain the desired short-range products. Typical flowsheets are given in Figs. 11 to 13.

Tennessee Coal, Iron & R.R. Co., Fig. 11 (*139 #9 J 29*).

Location: Dolonah, near Bessemer, Ala.
Crude: Dolomite.
Capacity: 125 t.p.h. of stone as 4 1/2~3/4-in. lump for fluxing in iron blast furnaces, and 3/4~1/8-in. screenings for bottom (raw or calcined) in open-hearth furnaces.
Building: Flat site. Steel structure substantially without cover.
Power: Transmission to plant at 44,000 volts; motors 25-hp. and up, 2,300-v.; smaller, 220-v.

Legend for Fig. 11:

1. 3-cyd. electric shovel; 10-ton side-dump cars by steam locomotives in 5-car trains; incline, quarry cars hoisted one at a time by remote control from dump station, 350-hp. motor; dump hopper.
2. 1 @ 42-in. gyratory crusher, 4-in. closed setting.
3. Belt conveyor.
4. Vibrating screen, 2 3/4-in. sq. opening, high-pressure sprays.
5. 1 @ No. 8 gyratory crusher, 2 3/4-in. open setting.
6. 2 vibrating screens, 3/4-in. sq. openings, high-pressure sprays.
7. Vibrating screen, 0.09-in. aperture; for dewatering.
8. Sump tank and sand pump.
9. 1 @ 42×16-in. rolls, 9/16-in. set.
10. Vibrating screen, 0.12-in. sq. aperture.
11. About 15% of material quarried.

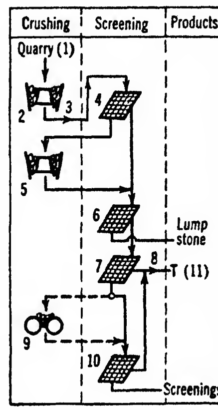


Fig. 11. Tennessee Coal, Iron & R.R. Co.

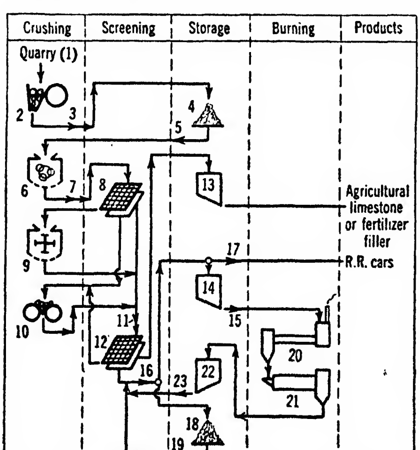
Summary. Two-stage open-circuit crushing in gyratories to limiting flux-stone size; screening at 4 1/2-, 3/4-, and 1/8-in. sizes for the desired products.

Valley Dolomite Corp., Fig. 12 (*33 #10 PQ 56*).

Location: Bonne Terre, Mo.
Capacity: 300 t.p.d. clinkered dolomite.
Crude: Self-fluxing, massive, badly faulted.
Products: Agricultural limestone, clinkered dolomite.



Legend for Fig. 12:

1. Diesel shovel (#75 Lorain crawler); 5 3/4-ton trucks, 1,000 ft.; pan feeder.
2. 1 @ 28×36-in. jaw crusher, 3-in. open setting.
3. 1 @ 24×76-in. belt conveyor.
4. Stockpile, 480 tons live capacity; 1 @ 30-in. ×6-ft. pan feeder. Capacity to this point 100 t.p.h.
5. 1 @ 24-in.×48-ft. belt conveyor. Capacity screening and fine crushing 60 t.p.h.
6. 1 @ 36×42-in. American ring-roll crusher, 1-in. grate setting.
7. 3 @ 24-in. conveyors, 13 1/2, 78, and 59 ft. long, in series.
8. 1 @ 4×14-ft. Symons 2-deck screen, 1-in. and 1/2-in. apertures.
9. Hammer mill.
10. 1 @ 42×18-in. Traylor rolls.
11. Elevator.
12. 1 @ 2-deck Niagara screen, 1/2-in. and 6-m. screens.
13. 1 @ 75-ton bin.
14. 1 @ 800-ton 2-compartment bin.

Fig. 12. Valley Dolomite Corp.

Legend for Fig. 12—Continued:

16. 1 @ 18-in.×310-ft. conveyor, 3 unloading points.
17. 1 @ 70-ft. car-loading conveyor.
18. 1 @ 6,500-ton stockpile; 3/4-cyd. scraper.
19. Bucket elevator.
20. 2 @ 7 1/2×7×125-ft. and 1 @ 9 1/2×8 1/2 ×150-ft. rotary kilns; linings 7 ft. 70% alumina brick, 22 1/2 ft. of forsterite or magnesite, 7 ft. high alumina brick, balance cold-zone brick; fired from individual coal mills drawing hot air from coolers (21). Kiln temperatures, 2,850 to 2,900° F.
21. 1 @ 7×65-ft. and 1 @ 6×60-ft. rotary cooler.
22. 1 @ 300-ton circular and 1 @ 400-ton conical steel bin.
23. 1 @ 78-ft. conveyor.

Summary. Four-stage crushing in jaw crusher, impact mills and rolls to 1/2-in.~6-m. kiln feed; undersize to agricultural stone.

Birmingham Slag Co., Douglas Dam plant, Fig. 13 (*45 #12 RP 54*).

Location: Douglas Dam, Tenn.
Capacity: 550 t.p.h. graded unwashed products.
Crude: Dolomite.
Products: 6~3-in. (cobbles); 3~1 1/2-in. (coarse); 1 1/2~3/4-in. (medium); 3/4-in.~4-m. (fine); sand.
Storage: Aggregate, 106,000 tons.
Distances: 1/2 mi. by 36-in. conveyor from stockpiles to dam site.
Arrangement. The successive screen-crusher units between stockpiles are placed in separate buildings adjacent the piles to which they stack; the stockpiles themselves are strung out in a line over a conveyor tunnel.

Legend for Fig. 13:

1. 3- and 3 1/2-cyd. shovels; 15 Koehring Diesel Dumptors and end-dump Autocars, 6- and 4-cyd.
2. 1 @ 42-in. A-C gyratory, 6-in. set.
3. 1 @ 42-in.× 165-ft. belt conveyor.
4. 1 @ 7,000-ton surge pile, <8- or 10-in. stone.

31. Variable split according to sand requirements.
32. 1 @ 24-in. conveyor.
33. Screw conveyor.

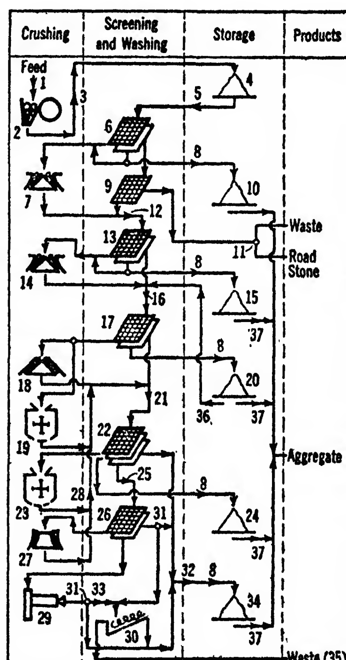

Fig. 13. Birmingham Slag Co., Douglas Dam plant.

Legend for Fig. 13—Continued:

34. Sand storage, 50-ft. max. height; Sauerman hoist with 1-cyd. bottomless Crescent bucket for blending and moving sand. Sand specifications are: modulus 2.3 to 3.2; size range:

Mesh..............	4	8	16	30	50	100	200
% passing..........	95–100	75–90	50–70	30–50	15–30	8–13	*a*

a Not more than 60% of the 100-m.

35. Tonnage small.
36. By 24-in. conveyor as needed for additional sand.
37. 36-in. tunnel conveyor under stockpiles; to batching bins, with intermediate washing of aggregate size over a vibrating screen, if desired.

Summary. Graded crushing in 8 circuits (7 open) to produce stone and sand, after initial discard of clay and unsound stone at about 1/2-in.

15. FELDSPAR

Occurrence and properties. About 60% of all igneous rocks is feldspar, but the commercial sources are granitic pegmatites. Deposits considered workable are those that yield large crystals by hand picking; most occurrences are very pockety. Commercial feldspars are intergrowths of at least two species of feldspar, chiefly the potash spars (orthoclase and microcline, $KAlSi_3O_8$) and soda spar (albite, $NaAlSi_3O_8$). Soda spars usually contain lime spar (anorthite, $CaAl_2Si_2O_8$) and there is a whole series of soda-lime feldspars called plagioclase, ranging in composition from albite through oligoclase, andesine, labradorite, and bytownite to anorthite. Perthite is an interlamination of orthoclase and albite. GRAPHIC GRANITE OR CORDUROY SPAR is an intergrowth of feldspar and quartz (characteristically in the ratio of 3 : 1); CORNWALL STONE is a natural mixture of feldspar, quartz, and kaolinite; a similar synthetic mixture, including some fluorspar, is made and marketed in the United States as CAROLINA STONE. NEPHELINE ($K_2Na_6Al_8Si_9O_{34}$) is a feldspathoid mineral occurring in coarse-textured syenitic rocks. Orthoclase is monoclinic; the other principal feldspars are triclinic; the whole group has the same HARDNESS (6 to 6.5); SP. GR. varies from 2.56 for potash spars to 2.60 for albite and 2.76 for anorthite; MELTING POINTS of the respective minerals are 1,200°, 1,110°, and 1,532° C.

Uses. In 1937, 51% of domestic sales of ground spar was for glassmaking, 37% for pottery, 9% in enamels, and 3% for miscellaneous purposes, including porcelain and other ceramic uses as well as abrasive-wheel binder, poultry grit, roofing granules, and cast stone. Feldspathoid minerals, notably nepheline syenite, albite syenites, rhyolite, volcanic ash, and even synthetic slags or wastes from certain chemical processes, may replace feldspar in glass and in pottery and enamels.

Production. The United States is by far the largest producer of feldspar. Domestic production of crude feldspar was 26,462 long tons in 1912, 236,108 tons in 1928, 117,281 tons in 1932, 268,532 tons in 1937, when North Carolina furnished 35%, Colorado 16%, South Dakota 15%, and New Hampshire 10%. North Carolina and Virginia spars are milled almost exclusively in those states or at Erwin, Tenn.; mills are also located in other leading mining centers as well as in Trenton, N. J., and East Liverpool, Ohio. Mills in Rochester, N. Y., northern Ohio, and Minnesota grind Canadian spar, much of which is shipped to the United States. European needs are supplied principally by Sweden and Norway.

Selling. Crude feldspar is sold mostly to merchant grinding mills situated near the mines or where milling-in-transit freight rates favor shipment to more than one consuming center. Prices at mills range from $2 to $7 or more a long ton; the average for all domestic crude spar, f.o.b. mine, in 1937 was $5.15. Owing to the multiplicity of products, differing greatly in chemical composition and size specifications, prices of ground feldspar vary over wide limits; in 1937 the average sales realization ranged from $7.05 per short ton in Colorado to $19.56 in New Jersey. Typical quotations f.o.b. mills in that year showed $12.50 a short ton for granular 20-m. glass spar and $17 to $19, respectively, for <200-m. potash and soda spar. Owing to freight and other charges, prices in Trenton or in Ohio points usually run $5 to $6 a ton higher than in North Carolina or New Hampshire. Western mill prices are even lower.

No definite standards exist for crude spar. The industry has accepted a commercial standard (CS23–30) published by the National Bureau of Standards, which classifies ground spar upon chemical composition and fineness of grinding. The National Feldspar Association has published a modified and less involved classification based upon use. Generally speaking, the better quality of crude spar in a given district is No. 1 and that carrying more free quartz is No. 2. Any material carrying more than about 25% quartz or badly iron-stained, if salable at all, may be called No. 3. Both No. 1 and No. 2 spar should be sufficiently free from iron to burn to a good white color, free from specks. In one district a product containing as much as 10 or even 15% quartz may be classed as No. 1, whereas in another this grade must be almost free from quartz. Dental spar is the highest quality of selected pure potash spar crystals; it commands a high premium but is marketed in very small quantities. For glassmaking, granular or semigranular spar (usually <20-m. and preferably free from dust) is prepared, low in iron (preferably 0.08% Fe_2O_3); it is desired mainly for its alumina which is higher in soda spar. Since soda is at least as acceptable as potash, nepheline syenite is coming into wide use; it sells for more per ton because it carries more alkalies and more alumina. In pottery spar, the potash-soda ratio is very important; too high soda is undesirable for most ware; cannot be tolerated for high-tension electrical porcelain or floor tile; even for general whiteware twice as much K_2O as Na_2O is

demanded. For making pottery glazes, on the other hand, a high soda spar, as low as 1 : 1, is generally specified. Low iron and good fired color are important in all pottery spar and the top limit of 20% free quartz is much reduced for better grades of ware. Most pottery spar is fine-ground, much of it <325-m., although <200-m. material is sometimes specified. Enamel spar receives an intermediate grind, usually <140-m., although all grindings from 20- to 200-m. may be specified; emphasis is placed on uniformity of composition and high potash content.

Abrasive-wheel makers may take 20 to 25% free quartz but not over 3% Na_2O; scouring-soap makers, too, want high potash spar as a rule although they are not so particular about mica as the glass or ceramic trade. Mixed products, carrying much quartz or more than traces of other mineral impurities, are difficult to sell, although they may be used for roofing granules, concrete aggregate, stucco, poultry grit, and miscellaneous abrasives and fillers.

Treatment. In Europe, feldspar is sometimes ground wet in pan mills; in the United States and Canada continuous dry grinding in pebble mills, with air separation, is standard practice. High-intensity magnets remove not only abraded iron but also biotite, garnet, tourmaline, and even some muscovite. Spar is hand sorted at the mines, forked to reject fines, and charged to the grinding mills. Mine dumps often carry 50% or more feldspar; flotation and agglomerate-tabling are both available to increase recoveries. Electrostatic separation has been tried but is not employed commercially at present. Blending of spar from different mines is common; one plant has 43 bins and additional ground storage for keeping separate 20 or more kinds of spar.

Tennessee Mineral Products Corp., Fig. 14 (*IC 6488*).

Location: Minpro (near Spruce Pine), N. C.

Crude: Raw spar from company mine and from about 60 other mines; average max. size is 6-in., some 200-lb. lumps received; bulk of fines removed. Range of typical analyses: SiO_2, 62 to 74%; Al_2O_3, 16 to 25%; Fe_2O_3, 0.06 to 0.17%; CaO, 0.2 to 4.9%; MgO, trace to 0.07%; K_2O, 13 to 12.4%; Na_2O, 1.5 to 8.2%; cone fusions, 5 to 9 1/2.

Labor: 1.9 man-hr. per ton.

Power: 48.5 hp-hr. per ton.

Distances: Motor truck and wagons, average haul for crude 6 mi., max. 18 mi.; railroad from greater distances.

Cost per ton (1929): To mixing bins (17), 43¢; blending charges at mixing bins, 9¢; fine grinding, 74¢; loading and shipping, 19¢; total $1.45. Labor, 47%; power, 31%; supplies and repairs, 16%.

Grinding costs (1929) to different sizes:

Mog..........	20	40	60	80	100	120	140	170	200	230
$ per ton.....	0.63	0.73	0.78	0.81	0.83	0.85	0.88	0.95	1.10	1.37

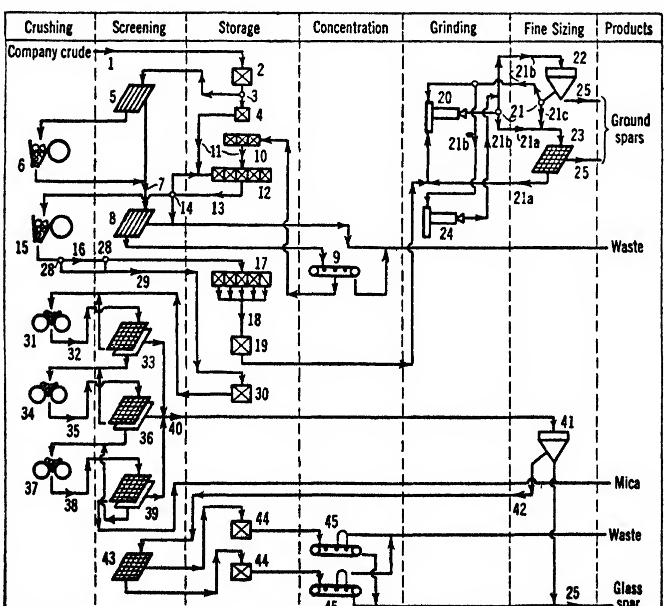

FIG. 14. TENNESSEE MINERAL PRODUCTS CORP.

Legend for Fig. 14:

1. Narrow-gage rail line, 3/4 mi., and cableway 650 ft.

2. 200-ton bin; 48-in.×10 1/2-ft. apron feeder.

3. Large pieces of No. 1 potash spar picked from feeder.

4. Small bin for spar from (3).

5. Grizzly, 4-in. spacing.

6. 1 @ 15×24-in. jaw crusher, 4-in. open setting.

7. 18-in. conveyor.

8. Grizzly, 1/2-in. aperture.

9. 1 @ 30-in.×138-ft. picking belt; 16 women and 3 men (2 cobbing) select 25 to 40 tons per 10 hr. from 70 to 80 tons feed to belt in order: first girl picks pure flint, 2 pick No. 1 soda spar; 2 or 3 pick No. 2 potash spar; one picks mica; balance pick all remaining spar (graded as No. 2 soda grade); 2 men cob at end to make No. 2 soda grade. See Table 7 for average analyses.

10. 13 @ 8-ton transfer bins chute-fed from picking-belt stations.

11. Hand tramming.

12. 43 crude-spar storage bins, 8,300-ton combined capacity. Also additional ground storage. About 20 different grades.

13. Wheelbarrows.

14. Fines dropped in forking to barrows screened on 1/4-in., undersize wasted; oversize returned to a separate bin.

15. 2 @ 10×16-in. Reliance jaw crushers, 1/2-in. set.

16. 1 @ 70-in.×30-ft. direct-heat countercurrent Ruggles-Coles rotary drier, 4 1/2-in. silex lining laid with 10 lifter courses; 5 1/2 r.p.m.; 17 lb. coke per ton; capacity 10 t.p.h. from 8% to <0.5% moisture; draft carried to remove bulk of <40-m. comprising mostly impurities; dust to 8-ft. cyclone; bucket elevator, 14-in. conveyor; swinging-chute sampler, 2% cut (sample to rolls and another swinging sampler taking 5% cut); bucket elevator; shuttle conveyor.

17. 29 @ 80-ton mixing bins. Material held in bins until analysis is completed. Drawn on charge specifications from chemical laboratory.

18. 330-lb. barrows, drawn in rotation to aid in mixing; elevator.

19. 50-ton surge bins; James automatic belt feeders.

One of three similar grinding units (20 to 27)

20. 1 @ 8-ft.×48-in. conical pebble mill, silex lining (9,100 lb.); 27 to 28 r.p.m.; 12,800 lb. 4-in. Danish pebbles.

21. Optional according to product being made; for <20-m., routing is along 21*a;* for <120-m. or finer, routing is along 21*b;* for <40- to <100-m., routing is along 21*c* with suitable limiting screen on (23).

22. 1 @ 14-ft. Gayco air classifier (20 hp. motor) for <120-m. separation and finer; see Table 8.

23. James vibrating screen; covering 20-m. to 100-m. according to product; see Table 8.

24. 1 @ 4×16-ft. pebble tube mill, silex lining, takes about half of classifier return (increases circuit capacity about 8%).

25. Parallel; 2 @ 10-in. elevators; 2 samplers; 5 @ 50-ton shipping bins.

26. All chutes, feeders, etc., lined with silex or rubber.

27. Switch from one grind to another made by one of two following methods: (1) A neutralizer charge, of such composition that, when added in suitable proportions to the material running, will produce material of the composition desired in the following run, is started with the last part of the running charge and continued with it for the time required to displace the in-mill load. (2) Start neutralizer charge immediately after end of one charge and continue until mill discharge has an analysis corresponding to the following lot, collecting ground material separately in the interim. Method (1) is applicable when analyses of the two main charges are close together; method (2) when analyses are relatively far apart, or for charges being bagged as produced, when there is no opportunity to mix the change-over product into the entire lot. For detail of preparation and use of calibration curves for neutralizer feeding at this plant, see original article.

18. 2 as (16).
19. Alternative.
20. 1 @ 8-ft.×48-in. Hardinge mill.
21. 1 @ 14-ft. Gayco air classifier.
22. About 20% of feed, comprising about 2% from (5) and 6% each from (12), (16), and (18).

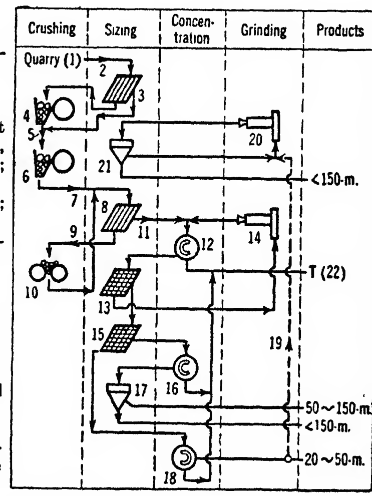

Fig. 16. American Nepheline Corp.

Summary. Reduction to <20-m. in three crushing stages and one grinding stage, all dry, with magnetic roughing in the grinding stage. Sizing to two <20-m. grades and cleaning of grades separately. Fine sand cleaned of <150-m. by air classification.

16. FLUORSPAR

Occurrence and properties. Fluorspar, or fluorite, CaF_2, is a not uncommon gangue with sulphide ores; barite is a common accessory mineral. It is transparent to translucent, frequently tinted or more deeply colored green, yellow, blue, lavender, or old rose; rare specimens may be orange to black and opaque. Crystals are commonly cubical but easily cleaved into octahedrons; SP. GR., 3 to 3.2; HARDNESS, 4; decrepitates when heated near its melting point at 1,270° to 1,387° C.; some varieties phosphoresce after moderate heating; a few show bluish fluorescence.

Uses. The principal main consumption (70 to 80%) is as flux in basic open-hearth steel making and foundries. The balance is used chiefly in manufacture of HF and chemicals or in ceramic industries (mostly for opal glasses or enameling). Smaller quantities are used in nonferrous smelting and manufacture of cement, calcium carbide and cyanamid, abrasives, heat-resistant brick, and carbon electrodes. Very small quantities are used in optical lenses and jewelry.

Production. Recent world production has ranged from 135,000 to 460,000 metric tons a year. The United States and Germany each produced nearly one-third; Great Britain, U.S.S.R., France, Italy, Spain, Newfoundland, Chosen, and China were important sources. Shipments of domestic spar in 1937 were 181,230 short tons; over 90% was from the Kentucky-Illinois field.

Selling. Commercial fluorspar is graded according to purity as ACID, CERAMIC, and METALLURGICAL SPAR. Acid manufacturers generally specify 98% CaF_2 and <1% of either $CaCO_3$ or SiO_2. For glass or enamel, fluorspar ordinarily should contain not less than 95% CaF_2 and not more than 3% SiO_2, 1% $CaCO_3$, and 0.12% Fe_2O_3. Steel makers demand 85% CaF_2, not more than 5% silica, and not more than 0.3% S, but lower grades are sometimes acceptable, especially in the West. Lead and zinc are objectionable for all uses. Acid spar is generally shipped as lump, metallurgical spar as gravel, and ceramic spar as ground. Acid-making requires finely ground fluorspar, but most manufacturers buy lump or gravel and grind it. The glass industry uses chiefly material ground 55% <100-m. and 15% <200-m. Finer ground material is used in enamels and to some extent in glass. Ground spar is shipped in bulk in paper-lined boxcars, in 125-lb. bags, or 450- to 500-lb. barrels.

Average price of domestic spar in 1909–13 was $6.39; in 1926–30, $18.49 per short ton, f.o.b. mines; in 1937, prices f.o.b. Illinois-Kentucky mines averaged about $19 for gravel and $27 for lump or ground spar, and f.o.b. western mines $13 for gravel and $17 for lump.

Treatment. Some residual deposits yield gravel spar by crushing and log-washing but most mines employ hand picking, washing, and concentration by jigs and tables. Flotation is a recent development; it yields higher-grade concentrate than gravity concentration (see Sec. 12, Art. 52). Decrepitation followed by screening has been tried at a few mills.

Hillside Fluorspar Mines, Fig. 17 (*IC 6621*).

Location: Rosiclare, Ill.
Capacity: 15 t.p.h.
Ore: Fluorite in calcite and limestone; small amounts of galena; no sphalerite: 50% CaF_2; 42% $CaCO_3$; 6% SiO_2.
Concentrate: 86% CaF_2, 13% $CaCO_3$, 0.92% SiO_2. Lead concentrate, 64.5% Pb, 5.2 oz. Ag.
Tailing (gravity): 22 to 25% CaF_2; 70% $CaCO_3$; 5 to 6% SiO_2.
Recovery (gravity): About 50%.
Ratio of concentration (gravity): 2 : 1.
Labor: 17.3 tons per man-shift.
Power: Company steam-generating plant (245 hp. connected in mill), 8.5 kw-hr. per ton.
Water: Local dam, supplemented in summer by 4,800-ft. 6-in. line from 4-in. 500-g.p.m. pump at Ohio River, total head 130 ft.; pumping cost 2.2¢ per 1,000 gal.; pumping from dam (1,000 ft.) to 15,000-gal. tank against 190-ft. head costs 3.6¢ per 1,000 gal.

12. 1 as (10); *a* = cells 5 and 6; *b* = cells 3 and 4; *c* = cells 1 and 2.
13. 1 @ 15 1/2×8-ft. thickener, 4 m.p.r., underflow 65% solids; 1 @ 4×2-ft. drum filter, 2 1/2 m.p.r., covered with 60-m. stainless-steel cloth, vacuum 20 in. Hg; cake <10% moisture; 1 @ 3×21 1/3-ft. direct-heat rotary drier, 3.2 r.p.m., oil-fired (3 to 4 gal. per ton of concentrate), 3-hp. motor; 1 @ 9-in. ×10-ft. screw conveyor, 16 r.p.m., 3/4-hp. motor; 1 @ 6×4-in.×33-ft. bucket elevator, 225 f.p.m., 2-hp. motor; 2 @ 15 1/3×20-ft. bolted-steel bins, combined capacity 425 tons. Shipment is by 5-ton dust-tight canvas-covered trucks and paper-lined boxcars.

Summary. One-stage crushing and one-stage closed-circuit ball milling to 65 *mog;* one-stage flotation roughing and 5 cleaning stages with one-step counterflows of all cleaner tailings.

17. FULLERS' EARTH AND BLEACHING CLAYS

Occurrence and properties. Fullers' earth is a water-worked clay which may be either calcareous or bentonitic; it occurs in beds, frequently 8 ft. or more thick. It is of two types: naturally active (FULLERS' EARTH) and active after acid-treatment (ARTIFICIALLY ACTIVATED EARTHS). The latter may be bentonitic, but natural fullers' earth and other clays are also acid-treated to enhance bleaching properties. Fullers' earth is typically nonplastic, has a large water content, and, if dried, adheres strongly to the tongue but does not slake readily. Best grades are light gray to brown in the raw wet state and nearly white after drying. Activable bentonites slake but do not swell like the Wyoming bentonites. The decolorizing power of percolation-grade clay is determined by passing standard oil through a column of the granular clay, measuring the volume of filtrate at a given color and comparing for color with a sample decolorized by clay of known bleaching power. Decolorizing power of contact-grade clay is measured by agitating with standard oil and comparing colors of filtrates; efficiency is expressed as per cent. of quantity of standard clay required to produce the same color. Unfortunately there is no single oil standard and relative values of competitive clays must be established on separate customer's stocks. Low oil retention of contact clay is second in importance only to bleaching power.

Uses. Over 90% of the domestic fullers' earth sold is used for refining petroleum products, especially lubricants; 5 to 7% for clarifying, bleaching, decolorizing, or filtering animal and vegetable oils; and only 1 or 2% for miscellaneous purposes. It is no longer used for fulling cloth. The principal object of applying bleaching earths is to remove color, but it also removes gum and other undesirable impurities and in edible oils it controls odor and taste. Bleaching clays are used in both contacting and percolation processes, the latter requiring a coarser, granular product.

Production. England was virtually the only source of fullers' earth until 1895, when American production began in Florida. Germany, U.S.S.R., France, and Japan are minor producers. Domestic output was a maximum at 335,644 short tons, valued at $4,326,705, in 1930; competition from activated earths and new oil-refining methods have since lowered the demand. World production of activated clay was at least 100,000 tons in 1937, of which nearly 75,000 tons was from the United States.

Selling. The market for natural bleaching clays is limited because many of the large oil companies mine their own earth. Bleaching clay is sometimes shipped loose in box or tank cars, but usually in returnable 135-lb. paper or burlap bags. Fine-grade clay (100-m. and finer) is used exclusively in contact-filtration plants. Average value of fullers' earth, f.o.b. American mines, was about $14 per ton in 1925–29 and $10 in the early 30's. Quotations in 1936–37 were: F.o.b. Georgia or Florida mines, $14.50 per ton for 30- to 60-m., $14 per ton for 15- to 30-m., $10 for 200-m. up, and $7 for 100-m. up; f.o.b. California mines, $17 to $21 for ground earth; f.o.b. Colorado, $9 per ton for crude. In 1938, German activated clay cost $70 per ton, delivered in New York; competitive domestic earth was $42 f.o.b. Los Angeles, Calif., or Jackson, Miss.

Treatment. Treatment of fullers' earth that is to be used in the natural state is relatively simple. A typical flowsheet for percolation-grade earth comprises cutting to <1-in., drying, graded crushing, and screening.

At ATTAPULGUS CLAY Co., Attapulgus, Ga. (*21 #9 PQ 62*), large tonnages are treated by air drying for 2 or 3 days to some 40 or 50% max. moisture; crushing, or, better, cutting, with disked rolls in two stages to about 1-in. max.; drying in a rotary drier to about 20% max. moisture; and then crushing in one closed- and 5 open-circuit stages with corrugated rolls, sifting out finished sizes on gyrating silk-cloth sifters after each step.

Temperature and time in drying must be controlled closely to avoid damaging clay. From 8 to 10% free moisture is left in contact clays, corresponding to a total volatile content of 15%. The adsorptive power of fullers' earth of the Georgia-Florida type (montmorillonite) may be increased 20% by an extrusion treatment, in which the clay is pugged and then forced through slots very much as meat is forced out of a domestic grinder. This not only makes a better product but permits virtually complete recovery of all of the clay in a granular form suitable for percolation.

Activated earth is made by agitating raw fullers' earth with sulphuric (or hydrochloric) acid for several hours at boiling temperature (212° to 220° F.), washing, filtering, drying, and pulverizing. The operation may be either batch or continuous.

18. GARNET

Properties. The garnet group comprises seven species of trisilicates of which pink, red, or black almandite ($3FeO \cdot Al_2O_3 \cdot 3SiO_2$) is most common and important. Andradite ($3CaO \cdot Fe_2O_3 \cdot 3SiO_2$) is also rather common and occurs in three varieties, *viz.*, melanite (black), demantoid (green), and topazolite (yellow green). Grossularite ($3CaO \cdot Al_2O_3 \cdot 3SiO_2$) may be white, pale green, or yellow. Uvarovite ($3CaO \cdot Cr_2O_3 \cdot 3SiO_2$) is emerald green. Pyrope ($3MgO \cdot Al_2O_3 \cdot 3SiO_2$) ranges in color from deep red to black. Spessartite ($3MnO \cdot Al_2O_3 \cdot 3SiO_2$) is brown to red. Rhodolite, a 2 to 1 mixture of pyrope and almandite, varies from pink to dark red. HARDNESS ranges from 6 to 7.5; almandite is sometimes rated 8. SP. GR., 3.5 to 4.2; almandite, 3.9 to 4.2. PERMEABILITY, see Sec. 13, Table 3. Some garnets are virtually infusible but almandite melts readily at 1,315° C. LUSTER is typically glassy; FRACTURE conchoidal; commercial varieties must be exceptionally tough; the shape of the fractured grains should be roughly equiaxed and chisel-edged, and light transparent red color is preferred by most consumers.

Occurrence. Garnets are found in a large variety of rocks; in some schists and gneisses they constitute from 10 to 50% of the rock over large areas. They are resistant to weathering and concentrate as rounded grains in river and sea sands. In Warren County, N. Y., garnet crystals may be several feet in diameter and are mostly an inch or more in diameter; the garnet must run as much as 6% (preferably 13%) of the rock mass (gneiss) to be workable. Common gangue minerals are hornblende, feldspar, and a little pyroxene, mica, quartz, and iron sulphide.

Uses. Garnets are well-known gemstones, particularly the blood-red pyrope, but the quantities so used are insignificant. Garnets have been displaced largely by sapphires in watch and instrument bearings. More than 90% of the garnet mined is used as abrasive, chiefly for coating papers and cloth, but increasing quantities are being used in sandblasting marble, slate, and other soft stone; for cleaning spark plugs; and for polishing and marking plate glass. Garnet-coated papers are used in this country mostly in the woodworking industry; in hardwood finishing garnet lasts longer and cuts two to six times as fast as quartz.

Production. Three mines in New York State, two of which are owned by one company, have supplied the bulk of the domestic production of garnet; additional supplies have come sporadically from New Hampshire and North Carolina. Production in the United States reached a peak of 9,006 short tons valued at $688,437 in 1923; in 1925, 7,429 tons valued at $712,853 was reported; in 1932 the figures were 1,950 tons worth $147,350; and in 1937 there was 4,863 tons valued at $382,535. For almost a decade the United States has been the only producer of mined garnet that is crushed and graded. (See Art. 1.) The domestic output of gem garnet has never risen above $2,000 and in recent years has been very small.

Selling. Abrasive-paper and cloth manufacturers in the United States prefer to do their own careful sizing and grading, so that sales are chiefly of ungraded concentrates, averaging better than 90% garnet, shipped in 100- or 150-lb. bags. Best-grade mixed concentrates have been quoted uniformly at about $85 per short ton f.o.b. mines; lower grades at $60; glass-surfacing grains around $40 to $45; the average of all shipments in recent years, however, has been around $80. Finished and graded grains sell for 4 to 8¢ per lb.; these are bought by European manufacturers of coated abrasive.

Treatment. The main objective in milling for the coated-abrasive trade is to avoid fines, but for plate glass and some other uses all sizes are eventually ground to pass 300-m. Stage crushing is the rule, and as garnet does not break down easily the undersize from a fine screen may often be discarded. Harz or James jigs are commonly used for concentrating all sizes over about 14-m. and sands are now tabled. The Hooper vanning jig, developed at a New York garnet mill, when preceded by a classifier, does as good or better work than tables but concentrates have to be removed by hand. Dry concentrators have been used in New Hampshire and North Carolina to eliminate mica and feldspar or quartz.

they are supplemented by magnetic treatment for recovery from kyanite schists. Electrostatic cleaning is effective, particularly for removing mica, but has been discontinued in favor of gravity methods after being tried at several plants. Recovery by froth flotation is practical on sizes under about 60-m. Sink-float roughing is used at BARTON MINES.

Barton Mines Corp., Fig. 21 (*153 A 429*).

Location: North Creek, N. Y.

Crude: Almandite with hornblende, feldspars, and small amounts of biotite, apatite, and garnet. Garnet content ranges from 5 to 20%; averages 10 to 12%. Garnet crystals average 4- to 6-in. and range from a fraction of an inch to 30- or 36-in.; most of them have a rim of coarsely crystalline hornblende. Sp. gr. of garnet is 3.8 to 4.1; hornblende, 3.1 to 3.2 (occasionally 3.4).

Legend for Fig. 21:

1. Jaw crusher.
2. Cone crusher, 1 1/4-in. product.
3. Mill ore bin; conveyor.
3a. Bucket elevator.
4. 1 @ 2-deck 4×10-ft. Ty-rock screen, 1/4-in. and 0.116-in. apertures.
5. 60 to 70% of mill feed.
6. 1 @ 5-ft. sink-float cone, 4-in. outside air-lift; ferrosilicon medium of 3.10 to 3.25 sp. gr. top (bottom 0.05 higher); consumption about 0.4 lb. per ton of mill feed.
7. 2 @ 4×10-ft. 2-deck Ty-rock screens in series, 1/4- and 1/2-in. (last 3 1/3 ft.) apertures on upper deck, 0.063-in. (10-m.) Ton-Cap on lower decks; screens divided longitudinally to serve for both float and sink.
8. 1 @ 30×14-in. Traylor rolls.
9. 6-ft. Allen cone (slime to waste); hydraulic classifier.
10. Hooper vanning jigs.
11. James jigs. Middlings crushed in rod mills and returned to (3a).

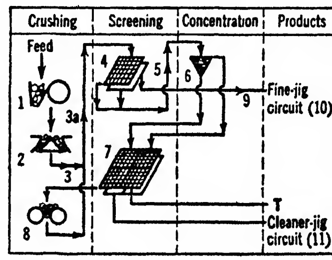

FIG. 21. BARTON MINES CORP.

Assays: >1/2-in. cone tailing, 0.3% garnet max.; <1/2-in. cone tailing (>1/4-in.), 3.0 garnet average, may run 5% on difficult ore. Cone tailings are 50 to 60% of total mill tailing and are about half-and-half >1/2-in. and <1/2-in.

19. GEM MINERALS

Properties. Color, luster, perfection of crystallization, and purity are the important properties of gem minerals. The precious stones are hard; of them only EMERALD (beryl, $Be_3Al_2Si_6O_{18}$) is under 9 on Mohs' scale, and the diamond (C) is the hardest substance known. Other precious stones are the colorless or blue (SAPPHIRE), and red (RUBY), or green (ORIENTAL EMERALD) crystalline varieties of corundum (Al_2O_3). Precious OPAL ($SiO_2 \cdot H_2O$) is also sometimes included. The semiprecious group includes specimens of almost any kind of mineral that has ornamental possibilities. Beryl, chrysoberyl, the feldspar gems (especially amazonite and moonstone), garnet, jade, lapis lazuli, peridot, spinel, topaz, tourmaline, turquoise, zircon, and the almost innumerable varieties of quartz gems all come in this class. The terminology is even more complicated than the mineralogy because the same stone often masquerades under a variety of names.

Uses. Off-color gem materials and fragments too small for use in jewelry are used as abrasives, for pointing tools, and for watch and instrument bearings. Semiprecious stones are used for vases, desk ornaments, and novelties of various kinds. Small pieces of colored stones, especially turquoise, are cemented together and made into various articles, and fragments of Oriental rubies, emeralds, and sapphires have been melted and thus manufactured into RECONSTRUCTED STONES.

Occurrence. Pegmatites are the original source of tourmalines, topaz, feldspar gems, quartz, zircon, emerald, and certain other gemstones, and basic rocks (pipes) and dikes have yielded diamonds and a few other gems. Gems occur in all rocks but, with a few notable exceptions, in such minor amounts that they cannot be worked economically in the mother rock and mining is largely confined to placer deposits where they have been roughly concentrated by streams or meteoric agencies.

Production. Statistics of production of gems other than diamonds (Art. 12) are meager. Turquoise and opal are fairly abundant in Nevada; sapphires have been mined on a variable scale in Montana; diamonds have been produced in Arkansas; amazon stone is shipped occasionally from Colorado and Virginia; California has reported kunzite and a variety of other gems; sporadic finds have been made in most States, but domestic production has never been large. The world's emeralds have come mainly from two districts in Colombia, the Russian Urals, and South Africa and are also mined in Brazil; rubies and sapphires from Burma, Ceylon, Siam, and Australia; turquoise from Persia, Tibet, Ethiopia, and the Sinai Peninsula; jade is a product of the Far East, current supplies coming principally from Turkestan and Burma; gem opals are mostly derived from Mexico,

Hungary, and Australia; and amber comes from the shores of the Baltic Sea. Even the semiprecious stones come mostly from one or two typical districts, although the source is not always well known; Brazilian onyx, for example, comes from Argentina.

Selling. Local jewelers are sometimes willing to purchase rough stones or to direct finders of occasional stones to lapidaries, wholesale houses, or dealers who handle mineral material for the optical, radio, and electrical industries. Abrasive and other industrial materials, however, are generally handled by special agencies or may be sold direct to large consumers. Prices are necessarily based upon private negotiation.

Treatment. Owing to the small scale of most gem-mining operations and also because so many of the operations are conducted in nonindustrial countries where native labor is cheap, production methods are typically primitive; they consist of hand panning or sluicing, followed by hand sorting. For gems that are typically heavier than quartz, the technique of diamond washing (Art. 12) may be applicable.

Industrial sapphires are produced in Montana and elsewhere by placer mining, often with gold as a joint product. Most industrial corundum jewels for watch, chronometer, and instrument bearings, however, are synthetic stones, made by melting Al_2O_3 containing a trace of coloring oxide in an oxy-hydrogen flame (Vermeuil process).

20. GRAPHITE

Properties. Graphite is one of the three principal forms of carbon. It is soft, black, unctuous (greasy), virtually infusible, resistant to most chemicals, a good conductor of heat or electricity, and a good lubricant. Actually all graphite is crystalline, but fine-grained graphite is commercially described as amorphous, grading on the one hand into anthracite coal and on the other into crystalline graphite. The latter term includes both flake graphite, which occurs in flakes or scales (lamellar), and other forms (such as lump, chip, and dust), produced principally in Ceylon and known as vein graphite or PLUMBAGO. Amorphous graphite may be called BLACK LEAD, and the term "graphite" is restricted by some to the crystalline flake mineral, though such usage is by no means universal. The SP. GR. is 2.1 to 2.3, intermediate between that of charcoal (1.3 to 1.9) and diamond (3.5). HARDNESS is 1; LUSTER is metallic.

Uses. Crucibles, retorts, ladle stoppers, and other graphite-clay refractories consume a substantial quantity of high-grade crystalline graphite. The leading use at present is in foundry facings; amorphous and, sometimes, artificial or manufactured graphite is used, as well as dust from crystalline grades. Pencil leads are made principally of mixtures of crystalline and amorphous graphite, particle size and color being important requirements. Both kinds of natural graphite and manufactured graphite are used in lubricants (which require grit-free material) and paints (for which high-grade material is unnecessary). Other uses include stove polish, dynamo brushes, dry batteries, boiler compounds; polish for glazing high explosives, shot, tea leaves, etc.; and as a filler or pigment in various articles.

Occurrence. The most common occurrence is in metamorphic rocks, especially schists, gneisses, and metamorphosed limestones; the content is rarely more than 6% graphite. Amorphous graphite may occur in coal strata. Other deposits are formed in limestone by contact metamorphism, and some pegmatites carry graphite. Schist deposits often carry other flaky minerals (mica, chlorite, and occasionally molybdenite) which are difficult to separate.

Production. World production was 221,000 tons in 1917; in the late 1920's it was about 150,000 tons. Ceylon graphite formerly comprised one-fourth the quantity and three-fourths the value of world production but now is less than 10% of the world tonnage and the relative value is much reduced. The highest-priced grades come only from Ceylon. Madagascar (flake), Ceylon (crystalline and high-grade amorphous), Chosen (chiefly amorphous), and Mexico (amorphous) supply most of the graphite that is valuable enough to bear cost of shipment overseas or long distances by rail. Central Europe has large supplies of low-grade flake and amorphous. The United States has never been a large producer and recently has produced mostly low-grade amorphous material for use in paint; it ranks second in consumption of high-grade graphite (30,000 tons in 1937).

Selling. Domestic supplies are principally imported. Mexican amorphous graphite, which carries a minimum of 80% graphitic carbon, is now the principal factor in domestic consumption; it costs $25 to $30 a short ton (including $14 freight) delivered in New York, in box cars, in bulk. Chosen amorphous is a trifle cheaper and both grades can be bought finely powdered for a little over $40 a ton, f.o.b. New York. Ceylon No. 1 lump is rarely sold now, but is quoted at 6 1/2¢ per lb., crude. Soft carbon lump, 90% C, also from Ceylon, is worth $50 to $70 a ton. Madagascar No. 1 flake, 85% C, sells in car lots (25 tons min.) for $75 to $120 a short ton, after paying freight (55s. to 65s. a metric ton) and import duty.

Any graphite containing less than about 80% C is difficult to sell, except perhaps for making paint. However, the percentage of C is not a sole criterion. Not only must the carbon be graphitic but other physical properties are quite as important as chemical composition. The value of flake graphite, for

example, depends largely upon the size and toughness of the particles and even an expert has difficulty in appraising the quality of a new product. Ordinary concentrates are likely to carry silica so imbedded naturally between laminae or pressed in during the grinding operation (PANCAKING) that it cannot be eliminated in subsequent cleaning operations without destroying the structure.

Treatment. Amorphous graphite that needs to be concentrated is not worth mining; preparation for foundry facing and paints usually requires grinding only; coarse impurities may be removed by screening or be dropped in air separators. Ceylon graphite is refined by hand methods, *i.e.*, screening, cobbing, wiping lumps with wet burlap, and removing small chips and dust by winnowing Flake from disseminated deposits must be concentrated; virtually every known concentrating device and combination of separating principles has been tried. The principal problem is to free the graphite without destroying the flakes or unduly reducing them in size, but this is difficult because crushing forces fine grains of gangue into the graphite. Probably in no other industry have so many mills been built that failed to make commercial recoveries. Many so-called secret processes have been developed and the mineral has gained the reputation of being difficult to separate. Actually it is one of the easiest minerals to segregate into a rough concentrate and one of the hardest to refine. It floats very readily, hence froth flotation is the simplest method for roughing. But cleaning by flotation is substantially ineffective without intervening treatment that liberates, and since such treatment leaves the gangue coated with graphite and hence floatable, subsequent separation is delicate, even if possible. In practice most refining is done by further grinding in rolls or buhrstones, followed by screening. The principle is preferential grinding of brittle gangue, leaving tough flake untorn, if possible; weak flake cannot stand such treatment. Seemingly, no mechanical process will yield flake graphite of extremely high purity; high-priced products may be purified chemically, SiO_2 being eliminated with HF or, occasionally, by fusion with an alkali such as Na_2CO_3. Few mills have succeeded in commercially unlocking large graphite flake from hard, fresh rock. Fig. 22 gives the flowsheet of one of the few mills that has operated on the North American continent for more than a very few years.

American Graphite Co., Fig. 22 (*120 P 567*).

Location: Ticonderoga, N. Y.
Ore: Flake graphite in quartzitic schist.
Capacity: 100 t.p.d.
Assays, % graphitic C: Feed, 5.5; concentrate (total), 86.5; coarse flake, 91.
Recovery: 87%.

28. Bin.
29. Bin.
30. Air classifier.

Summary. Two-stage open-circuit crushing to ball-mill feed; one-stage closed-circuit ball milling under conditions to encourage overflow of coarse flake; one-stage roughing flotation; five stages of cleaning, with regrinding of the >100-m. float after the first and third stages; all cleaner tailings counterflowed to the rougher.

21. GYPSUM

Properties. Gypsum, $CaSO_4 \cdot 2H_2O$, is a soft, usually colorless mineral, occurring compact or massive (also scaly, silky, or fibrous) and cleavable in three directions. HARDNESS is 1.5 to 2; SP. GR., 2.3. Dead-burned gypsum is identical in composition with anhydrite, $CaSO_4$, which is harder (H = 3 to 3.5) and slightly heavier (SP. GR. = 2.9 to 3).

Uses. Nearly 25% of domestic sales are raw gypsum for use chiefly as a Portland-cement retarder, and for grinding to LAND PLASTER, a soil sweetener and fertilizer employed principally on peanuts (for which purpose anhydrite also is acceptable), or for filler. More than 75% of the gypsum used in the United States, however, is calcined into plaster of Paris, which in turn is made into various kinds of prepared plaster and other products such as wall board. Small quantities of calcined gypsum are used for bedding plate glass and cut stone while they are being ground or polished; as a mold or cast in potteries, terra cotta works, and iron foundries; and for surgical and dental purposes, but the tonnage consumed outside of the building industry is relatively small. Pure white or attractively veined, fine-grained gypsum is called ALABASTER and may be fashioned into statuary, lamp bases, art goods, and novelties.

Occurrence. Selenite is a frequent gangue mineral in metallic ores but ordinarily does not pay to separate. Rock gypsum is found in beds of wide extent up to 50 ft. thick in many localities, so only those within fairly easy reach of populous consuming areas can be worked.

Production. Ordinarily the United States is the largest producer both as regards tonnage mined and value of products, with France second, the United Kingdom third, and Canada or Germany fourth. World production in 1937 was about 9,500,000 metric tons. Domestic production of crude gypsum was 3,058,166 short tons in 1937 compared with a peak of 5,678,302 in 1925. Imports of Canadian crude reached a maximum of 1,036,585 short tons in 1929 compared with 897,484 in 1937 and 634,423 in 1925. Gross value of sales of domestic and imported gypsum and products was about $39,000,000 in 1937, of which 860,825 short tons valued at $1,920,706 was sold raw and 2,645,081 tons (total weight of calcined gypsum, filler, paper, etc.) valued at $36,914,006 represented finished calcined products. The pre-depression peak gross value was nearly $50,000,000.

Selling. The gypsum industry of the United States is highly integrated and even the gypsum imported from Canada is mostly mined by the same companies that convert it into plaster. Much of the domestic gypsum sold to cement plants is screenings from lump material produced by companies that not only mine gypsum but also make plaster and often a complete line of gypsum products as well. Notwithstanding a trend to build calcining works at consuming centers rather than at the mines, and although Canadian gypsum is carried all the way to London as well as to Atlantic seaboard plants in the United States, very little raw gypsum actually comes into the open market.

The average prices of domestic raw gypsum, f.o.b. mines, have ranged from $1.75 to $2 a short ton for cement retarder and around $5 a ton for that sold for land plaster, whereas the average value of the various products made from calcined gypsum of domestic origin recently has been $15 a ton or more, although in 1937 the average value of STUCCO or calcined gypsum as it left the kilns was only $4.58.

Treatment. Crude gypsum containing any appreciable amount of impurities that would have to be separated is not considered commercial. Aside from screening to reject fines and clay, and crushing to about <1 1/2-in. for kettle feed, no beneficiation is considered possible. In the United States vertical cylinders or kettles (Fig. 23), mostly taking 10-ton batches, are ordinarily used for calcining. These are typically 8 to 10 ft. high, and 8 to 12 ft. in diameter; the steel shell is 3/8 to 3/4 in. thick and bottoms are cast iron or steel, 1 to 3 in. thick and arched over the grate. Flues may be passed through the shell of the kettle as well as between the shell and the enclosing brickwork. Paddles are provided to keep the gypsum in motion. After being previously warmed to 212° F. to drive out moisture, the kettles are slowly charged with ground gypsum and then heated gradually. At 230° F. the gypsum begins to boil violently and continues to boil until a little more than half its combined water has passed out as steam. The product so formed is FIRST-SETTLE PLASTER. If the temperature is raised above 270° F., boiling is resumed and more water passes off up to a certain limit, forming SECOND-SETTLE PLASTER. At temperatures much above 330° F. the plaster may be overheated and become dead-burned and worthless. The temperatures at which these transformations take place, however, vary, and the size of kettle

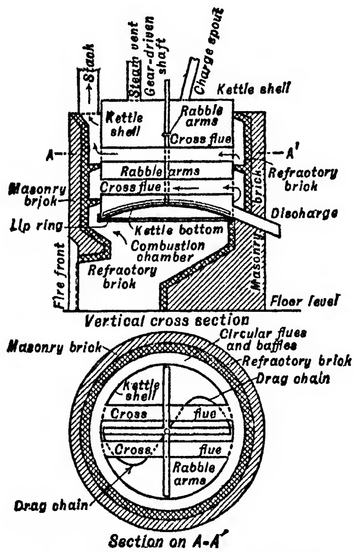

FIG. 23. Calcining kettle for gypsum.

Summary. Two-stage crushing to <40-m. in single-roll crusher and hammer mill; calcining; tube-mill grinding to 300-m.

22. ICELAND SPAR

Properties and uses. Iceland spar is a variety of calcite, $CaCO_3$, characterized by exceptional purity, transparency, perfect crystalline structure, and marked double refraction. Good optical spar splits in three directions at oblique angles, forming a perfect rhombohedron. The most important use is for Nicol prisms, which are essential parts of every polarizng microscope, and in special instruments such as saccharimeters, dichroscopes, photometers, colorimeters, and polariscopes. Owing to its chemical purity, Iceland spar is used by manufacturing chemists and laboratories for standardizing solutions.

Occurrence. Deposits are rare. Principal deposits are pockets or small masses of crystal aggregates mixed with clay in cavities of basic igneous rocks. The spar mine in Iceland, for many years the only source, has been virtually abandoned as the material became lower in grade.

Production and selling. South Africa was the leading producer from about 1921 until the late 1930's. In 1939, an important discovery was made in New Mexico. Other deposits have been reported; most of them have not proved commercial, although small shipments have been made intermittently from Spain and elsewhere. Before 1914, German firms supplied virtually all the world's Nicol prisms so that the demand for optical calcite in the United States and other countries was almost nil. American consumption is still small, probably not more than 300 lb. annually in the late 1930's; foreign consumption is normally considerably greater, but no figures are available.

Prices of rough optical spar fluctuate from $7 to $35 a pound. Standardizing spar and ordinary museum specimens are worth $1 to $3 a pound. Optical spar must be water-clear, untwinned, free from incipient cracks or other visible defects. Pieces smaller than 1-in. length and 1/2×1/2-in. cross-section are rarely acceptable for optical use.

Mining and preparation. Preparation starts in the mine. Ordinary open-pit mining methods were used in Iceland, the country rock being broken by explosives, and clay pockets worked by hand to recover crystals which were later cobbed and broken into smaller pieces. Blasting, however, ruins much otherwise good material. One alternative to explosives in drill-holes is quicklime which is tamped around a wire. A cotton string saturated with water is substituted for the wire before stemming. Water from the wet

string slowly slakes the lime which expands enough to cause fracture. Channeling, wedging, and other methods such as are used for quarrying dimension stone or gem material may also be applicable. Each specimen must be examined from every direction. Imperfect portions of large crystals may be trimmed away, preferably by an experienced person. One misdirected blow may cause incipient fractures throughout the whole crystal. In shipping, each piece should be wrapped separately to prevent damage.

23. KYANITE, ETC.

Properties. The three minerals kyanite (also spelled CYANITE), sillimanite, and andalusite all have the same composition $Al_2O_3 \cdot SiO_2$ but differ in mode of crystallization. Andalusite and kyanite revert to sillimanite when heated to between 1,350° and 1,400° C. Dumortierite, $8Al_2O_3 \cdot B_2O_3 \cdot 6SiO_2 \cdot H_2O$, despite the slightly higher Al_2O_3, boric acid, and water content and different appearance, is closely related in thermal behavior and has corresponding uses. All four minerals are converted above 1,545° C. to mullite, $3Al_2O_3 \cdot 2SiO_2$, and a liquid. Properties are summarized in Table 10.

Table 10. Properties of the kyanite minerals

Mineral	Crystallization	Sp. gr.	Hardness	Cleavage	Color
Andalusite...	Orthorhombic	3.1 to 3.2	7.5	Prismatic	Gray or green, red, blue tints
Dumortierite.	do.	3.25 to 3.35	7	Macro- and brachy-pinacoidal	Bright blue to green blue
Kyanite.....	Triclinic	3.5 to 3.7	4 to 7	Macro- and brachy-pinacoidal	Blue, gray, green, brown
Mullite......	Orthorhombic	3.156	6 to 7	....	White
Sillimanite...	do.	3.2 to 3.25	6 to 7	Macro-pinacoidal	White, gray, brown, green

Uses. Dumortierite and andalusite are used for the manufacture of porcelain spark-plug cores and sillimanite laboratory ware. Imported kyanite and some domestic is used in sillimanite brick. The principal use of all kyanite is in glass-plant refractories and refractory cement. Synthetic mullite, made from electrically fused diaspore and kaolin, is an important competitor of kyanite, being used for refractory porcelains as well as in glass tanks, saggers, muffles, and parts of high-temperature furnaces. Low-iron concentrates may be used in glass as a source of alumina, replacing feldspar.

Occurrence. Kyanite is a common mineral in crystalline rocks; the most important occurrences are in gneiss or schist where it may comprise 10 to 40% of the rock over fairly large areas. The most productive deposit so far has been that of CELO MINES, near Burnsville, N. C. The ore averages 15% kyanite but 26 different minerals have been identified in a single hand specimen. Andalusite is mined relatively extensively only near the Nevada-California border where it occurs in irregular segregations in lenticular quartz masses enclosed in sericite schist or in vertical veinlike deposits along with corundum and diaspore. Sillimanite occurs in gneisses, schists, slates, and hornfels; it is frequently associated with or grades into corundum. Dumortierite is not common but occurs in Nevada in masses in a quartz segregation in much the same way as andalusite. Mullite is a common and exceedingly desirable constituent of refractories but is rare in nature.

Production. None of these minerals was mined to an appreciable extent until after 1918. In 1937 the total domestic production, chiefly kyanite, may have been as much as 6,000 to 7,000 tons, and imports rose in that year to 7,674 short tons, all from British India. Consumption outside of the United States is not known but probably is very small.

Selling. No sillimanite is known to have been mined in the United States, and, since the consumption of andalusite and dumortierite has been almost exclusively by the company that mined it, kyanite is virtually the only one of the group that has appeared on the market; this market is still in the development stage. Prices have been the main deterrent to more widespread use of all of these minerals. When first introduced, about 1923, kyanite sold for $100 a short ton; by the end of 1934 CELO MINES, leading producer in the United States, was quoting $18 a short ton for 70 to 80% concentrates, grading up to $25 for 90%. An additional charge of $15 a ton was made for calcining. In 1938, North Carolina and Georgia concentrates of improved grade were quoted at $18 to $22.50 a ton. Imported kyanite is nominally cheaper; most of it comes as exceedingly hard, tough boulders from which large grains, desired by brickmakers, as well as fines can be made by crushing.

Treatment. In British India the kyanite and corundum boulders are selected by hand. At the Detroit, Mich., plant of the CHAMPION SILLIMANITE Co., the andalusite and dumortierite, selectively mined and hand-sorted at the company's California and Nevada mines, and bedded, is crushed, passed over a magnetic separator, sized, and sent to shipping bins.

Celo Mines, Inc., Fig. 26 (*Q; 138 #9 J 45*).

Location: Burnsville, N. C.
Ore: Gneiss. Kyanite, 15 to 20%, finely disseminated garnet, 10 to 15%; quartz, 25 to 30%; mica, 35 to 40%; sulphides, 2%.
Capacity: 175 t.p.d.
Assays: Feed as above; concentrate, 85% kyanite.
Recovery: 80%.
Ratio of concentration: 8 : 1.
Water from stream 1/2-mi. by pump (15-hp.); consumption, 7 tons per ton milled; 75% re-used.
Power purchased at 33,000 volts; transmitted 2 mi. at 2,300 volts, motors, 220- and 440-volt, 60-cycle; consumption, 48 hp-hr. per ton milled.
Labor: 15 tons per man-shift operating.
Running time: 75%; 80% possible. Principal cause of loss is hammer mill repair.
Mill building: Steeply sloping site; timber frame and sheet-metal enclosure; wood floors; unheated.
Distances: 1,500 ft. mine to mill by 3-ft.-gage tramway; 3 mi. to railroad.

31. 1 @ 10-ft. Sturtevant separator.

32. If only to 48-m.

Fig. 27. Kyanite Products Corp.

Summary. Washing; three-stage crushing to 1/8-in.; one-stage closed-circuit (screen) grinding to <35-m.; desliming; flotation of deslimed sand; magnetic separation of dried concentrate; ± calcining and /or grinding.

At the Georgia plants of Southern Mining & Milling Co., kyanite-mica schist is treated in a special mulling operation so that very little kyanite is broken finer than 10-m., though subsequently it may be ground to 20-m. for sale. Roofing mica and graphite are recovered from the overflow and the kyanite removed from the mullers is screened to eliminate sand. The process is patented (*U. S. patent 2,105, 597*). According to Boyd (*19 Bul ACerS 461*), the soft kyanite schist, roughly hand-sorted, is passed over a 2-in. grizzly and crushed in a 10×12-in. crusher set at about 1 in. All undersize is sluiced to a variable splitter and thence to four 16-ft. mullers, each having two 1,000-lb. rubber-covered rollers and turning 11 r.p.m. Discharge is over a 36-in. center rim. Additional water is added to each muller, and mica and graphite overflow. Each muller receives about 1 1/4 tons per hr. for 3 hr. and operates 1 hr. more to clean kyanite-sand residue, which is finally washed through 1 1/2-in. screen and elevated to a vibrating screen with 10-m. and 20-m. decks. Oversize is remulled and <20-m., chiefly sand, is wasted. Intermediate screen product goes to a mica-tailing table.

Remulling differs from primary mulling in that it allows more scuffing and less mashing; less mica is present and less water is required to remove the mica, allowing 50-m. sand to remain in the muller for better action on the kyanite. When each batch is finished, the residue, containing 65 to 85% kyanite, is split on a 3/8-in. screen, oversize going to a coarse jig and undersize, after removing <16-m. waste sand, to a fine jig. Both jigs yield a 95% product, the chief impurity being quartz.

24. LIMESTONE

Properties. Calcite is the essential constituent of limestones. High-calcium limestones may consist almost entirely of $CaCO_3$. If 10% or more $MgCO_3$ is present, the stone is called magnesian or dolomitic limestone; when the $MgCO_3$ reaches 45%, it is known as dolomite. Siliceous or cherty, argillaceous, ferruginous, carbonaceous, or bituminous limestones are also distinguished; marbles are highly crystalline metamorphosed limestones; coral, crinoid, or coquina limestones are rocks made up almost entirely of shells, while chalk is a friable limestone composed largely of minute shells of foraminifera. Oyster-shell beds may be classed as unconsolidated limestones and, where extensive, are used commercially for like purposes. Onyx and travertine are limestones deposited from solution. The well-known Indiana limestone is oölitic and ultra fine-grained crystalline limestone, usually of drab or yellowish color; it may be classed (and used) as lithographic stone. Sp. gr. is usually slightly less than that of calcite (2.72) or dolomite (2.85); hardness is 3, but limestones range from chalk that is easily crushed in the fingers to indurated types as tough and almost as hard as trap rock. High-calcium varieties are readily soluble in weak acid; dolomitic only in strong acid.

Occurrence. Deposits of limestone occur in every state. Stone suitable for building is quarried in about half of them, and in some states hundreds of quarries produce crushed or pulverized limestone. Ohio, Pennsylvania, Michigan, New York, Illinois, and Indiana lead in production in about the order named. Most of the building limestone, however, originates in Indiana, and Missouri limestone and lime probably have widest industrial market due to purity. Pure calcite in large transparent crystals is found only in veins; optical grades (see Art. 22) are rare.

Uses. Limestone is the most useful of all rocks, and new uses for it are continually being developed. Roughly half the dimension stone and a good deal more than half of the crushed stone used for construction is limestone; further large tonnages are employed as feed to cement plants (Sec. 3A), as metallurgical flux, as fertilizer, in chemical works, and as a filler. See also Table 11.

Production. See Table 11.

Selling. Prices of crushed limestone vary with local conditions of cost and competition. Average annual values for the entire country have ranged from 90¢ to $1.19 per ton in recent years. Much fluxing stone is worth less than 50¢ a ton f.o.b. quarry, whereas Indiana limestone is worth over $1 per cu. ft. when cut, and at least 30¢ per cu. ft. or around $25 per short ton in rough blocks. Lime also varies greatly in price, but the average for all shipments in the United States in 1937 was $7.31 per ton at kilns.

Treatment comprises cutting for dimension stone (Art. 40); crushing for broken stone, agricultural stone, stone sand, and limestone dust (Art. 41); and burning for lime.

Ohio Marble Co., Fig. 28 (*33 #3 PQ 41*).

Location: Piqua, Ohio.
Capacity: 200 t.p.h. of flux stone; somewhat less on roadstone.
Crude: Limestone.
Products: 4~1 1/2-in. flux; 2 1/2~2-in. flux; 2 1/2~1 1/2-in. roadstone; <1 1/4-in. screenings.
Buildings: Steel and concrete.

Legend for Fig. 28:

1. 2-cyd. shovels; 5 @ 5 1/2-cyd. end-dump trucks, 3/4 mi.
2. 1 @ No. 30 A-C gyratory, 4-in. open setting.
3. 1 @ 30-in.×80-ft. inclined chain-bucket elevator.
4. 1 @ 50-ton steel surge hopper; vibrating feeder; 36-in.×40-ft. belt conveyor; 34-in.×90-ft. chain-bucket elevator.
5. 1 @ 4×12-ft. Simplicity vibrating screen, 1-in. aperture.
6. 1 @ No. 6 Traylor TY reduction gyratory.
7. 1 @ 24-in.×60-ft. belt-bucket elevator.
8. Direct to (4) when flux stone is being made.
9. 2 @ 4×10-ft. Simplicity screens, 1-in. and 1 1/4-in. sq.-perforated plate.
10. Bins, 150-ton each; discharge to cars or trucks.
11. 1 @ 4×12-ft. 3-deck Simplicity screen, 2 1/2-, 2-, and 1 3/4-in. perforated-plate cover.
12. Alternative by flip-flap in discharge chute of elevator (4).
13. 1 @ 24-in.×50-ft. belt conveyor; 1 @ 20-in.×35-ft. chain-bucket elevator.
14. 1 @ 4×8-ft. 2-deck Simplicity screen, 1-in. and 3/4-in. perforated plate.
15. 1 @ 14-in.×25-ft. belt conveyor.
16. 1 @ 3×10-ft. Low-head screen, 3/16-in. aperture.
17. Alternative or in parallel.
18. 1 @ 4×8-ft. 2-deck A-C vibrating screen; top deck has perforated-plate cover, apertures range from 1-in. to 3/8-in.; bottom deck, 2 sizes of aperture down to 3/16-in. minumum.
19. Alternative.
20. 8 @ 200-ton concrete bins loading to cars or trucks.
21. Sturtevant rock-emery mill; two ball-tube mills; Hum-mer screens; rotary drier; air-sizers; bag packers.

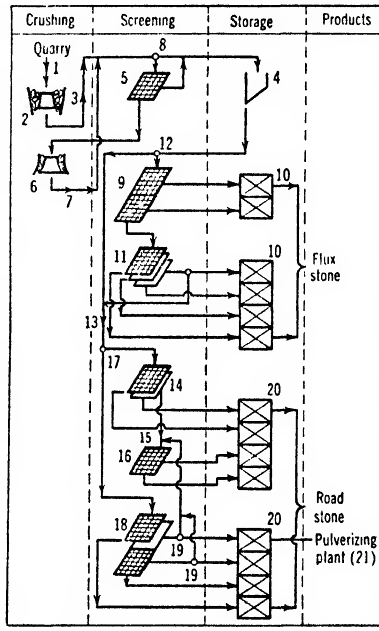

Fig. 28. Ohio Marble Co.

Summary. Dry processing for upwards of 14 flux stone and roadstone sizes and for grits and dust for poultry and cattle, fillers, concrete finishes, etc.

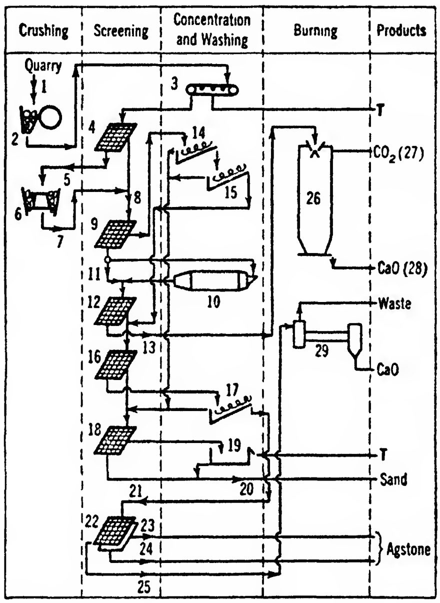
At Inland Lime & Stone Co., Port Inland, Mich. (*21 #8 PQ 53*), limestone is crushed at the rate of 750 t.p.h. from large steam-shovel size to six grades between 14-in. and 1/8-in. in a sequence comprising a 10-in. grizzly, a 60-in. gyratory, 2 @ 6-in. live-roll grizzlies, a 20-in. gyratory, a 7-ft. standard cone crusher, and a battery of vibrating screens with 2 1/2-, 1 1/4-, 5/8-, and 1/8-in. apertures with conveyor provisions for closing circuit on the cone crusher from both the 2 1/2- and the 1 1/4-in. screens; <1/8-in. material is wasted. Open storage is provided to carry over the closed season on Lake Michigan and permit loading out during open season at 3,000 t.p.h. Roller and ball bearings are used throughout the plant, upward of 20,000 units in all.

At Liberty Limestone Corp., Buchanan, Va. (*44 #8 RP 29*), a hard dolomitic limestone is processed for ballast, aggregate, stone sand, and agricultural limestone. Flowsheet permits much by-passing and variation in products by changing screen covers. Crushers are a 24×36-in. jaw crusher, a 36-in. Gyrasphere, and a No. 25 Kennedy gearless in sequence, with 4×12-ft. @ 3-deck Niagara screen between Gyrasphere and Kennedy crushers, and a 4×10-ft. @ 2-deck Niagara following the Kennedy. For ballast the flow is from the jaw crusher direct to the 3-deck screen; otherwise the Gyrasphere intervenes. Agricultural limestone (<10-m.) is made from dry <3/4-in. stone in a Kent mill or a Sturtevant ring-roll mill in closed circuit with 10-m. vibrating screens; if the feed is wet, it is sent to a 5-roll Raymond high-side mill working with hot air. Stone sand is made from sound stone (not screenings) in dry rod mills in closed-circuit with vibrating screens and an air separator; dusts come from the air separator.

Mathieson Alkali Works, Fig. 29 (Ref. as for Fig. 30).

Location: Saltville, Va.

Summary. Two-stage crushing at quarry, with intermediate scalping, to <6-in.; splitting <6-in. material at 3-in.; scrubbing 6∼3-in. and burning in shaft kilns to produce



Legend for Fig. 29:

Summary. Two-stage screen washing of whole dredged shell; burning in a long rotary kiln with recuperation on the lime; slaking and rejecting overburned waste by fine wet screening.

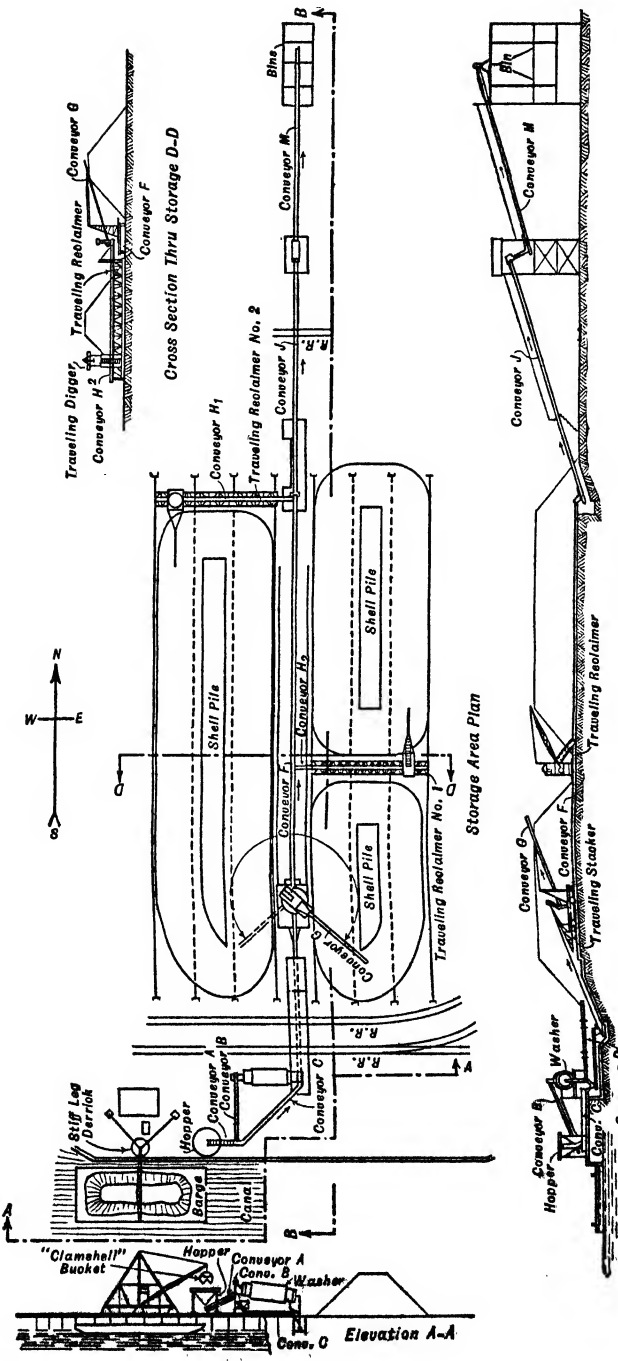

Fig. 31. Storage and transport at Mathieson Alkali Works, Lake Charles plant.

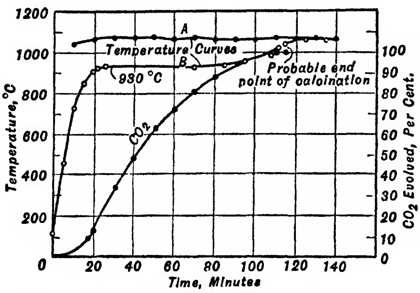
Lime Burning

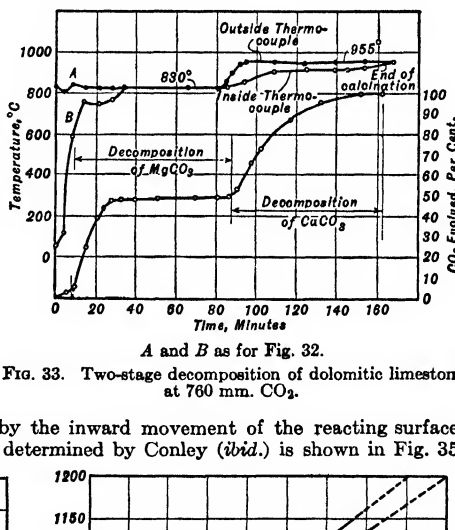
When carbonates are heated sufficiently they decompose, evolving CO_2 and leaving behind the corresponding oxides. The temperature of dissociation depends upon the carbonate, which determines the dissociation pressure, and upon the partial pressure of CO_2 in the surrounding atmosphere. The dissociation pressure of $CaCO_3$ becomes 760 mm. at about 900° C., *i.e.*, dissociation occurs at this temperature in an atmosphere of CO_2. The corresponding temperature for $MgCO_3$ is about 760° C. The temperature for dolomites depends upon the relative percentages of the two carbonates present, the mixture tending to act as a double salt, giving decomposition temperatures lying between those for the pure carbonates (Porter, *Circ 337 USBS 8*). Temperature-time relation for the two stones are given in Figs. 32, 33. If, however, the partial pressure of CO_2 in the surroundings is less than 760 mm., as is invariably the case in an operating kiln where a CO_2 content of 40% in the gas is high, the initial dissociation temperature is lower. The relationship for $CaCO_3$ is given in Fig. 34 (Knibbs, *10 CLM 6*).



A, surface temperature; *B*, center temperature.

FIG. 32. Decomposition of high-calcium limestone at 760 mm. CO_2.

When a lump of stone burns without mechanical removal of the CaO as formed, this remains as a shell around an unaltered core, and the reaction interface proceeds inwardly through the lump as a relatively sharply defined surface which, by reason of an accelerated rate at the projecting edges and corners, tends to reduce the core toward a spherical configuration (Conley, *148 A 330*). As soon as the shell of lime reaches visible thickness, the CO_2 content at the reaction interface rises to 100%, with corresponding increase in dissociation temperature.



A and *B* as for Fig. 32.

FIG. 33. Two-stage decomposition of dolomitic limestone at 760 mm. CO_2.

Rate of dissociation, as measured by the inward movement of the reacting surface, increases with temperature. Rate as determined by Conley (*ibid.*) is shown in Fig. 35,

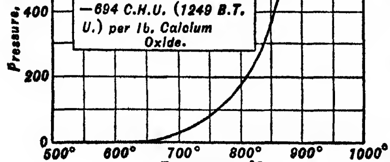


FIG. 34. Dissociation temperature *vs.* CO_2 pressure for calcium carbonate.

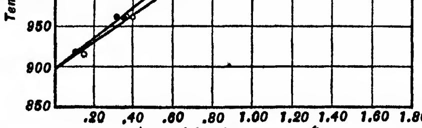

A, Experimental; partially calcined samples; *B*, calculated for complete calcination.

FIG. 35. Temperature *vs.* calcination rate for high-calcium limestone at 760 mm. CO_2.

curve *A;* curve *B* shows for comparison other rates calculated by a rate equation $R = (0.5254T - 470.2)/100$, in which R = rate of inward movement of the reaction surface in cm. per hr., and T = temperature *of the lump* in °C.

Burning temperature. The natural inference from the rate curve, *viz.*, that operating furnace temperatures should be as high as the linings will permit, must, however, be modified because excessive temperatures produce limes that hydrate slowly and incompletely. Such limes are called OVERBURNED. Overburned lime is denser than normal lime, the higher density corresponding to closer packing of the atoms incident upon larger crystal units (*42 #5 RP 40*). It also contains particles coated with, and to a certain extent impregnated by, glasses and/or compact crystalline shells, films, and granules which close the pores of the lime and hinder or prevent access of water in hydration. These films, etc., form owing to the fact that in practice all natural stone contains impurities having acidic characteristics (Fe_2O_3, Al_2O_3, SiO_2), which react at calcining temperatures with the basic oxides to form compounds fused at these temperatures. The amount of such compounds formed is greater the greater the amount of impurity (see Fig. 36) and the higher the temperature. There is practically no overburning at 1,000° C., even with long exposure. Hence operating temperatures are an economic compromise between the drive for high capacity per burning unit and the salability (or hydrate yield) of the resulting lime. Actual stone temperatures in operating kilns are not known. Such measurements as have been made are of gas temperatures. The range reported for burning high-lime stone in shaft kilns is from 1,250° to 1,650° C.; temperatures for dolomitic stone are lower. In general, also, temperatures for small stone of a given composition are less than for large.

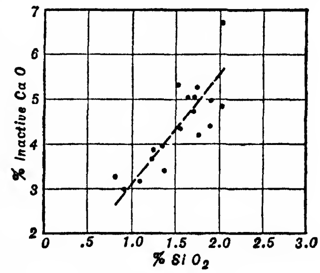

FIG. 36. Effect of silica in producing inactive lime.

Recarbonation occurs when lime at temperatures above 500° C. is exposed to an atmosphere containing CO_2. The reaction goes with increasing velocity as dissociation temperatures are approached. Furnaces are designed either to prevent contact with CO_2, or to chill rapidly through the recarbonation range.

Kilns

Kilns for lime burning are either of shaft (vertical) or rotary (horizontal) types; the former are used for small capacities, or where the demand is for lump lime; rotary kilns are usual for high capacities.

Shaft kiln consists essentially of a stack, relatively short as compared with its horizontal dimensions; of square, circular, or oval cross-section; with or without internal taper. Means for heating, charging rock, retaining rock in the shaft, and discharging must also be provided.

Shaft. Typical longitudinal sections, used with all forms of transverse section, are shown in Fig. 37. Each has advantages and disadvantages. Form *A*, usually circular, is cheapest to build, the charge falls freely unless there is considerable overburning, and there is a minimum of horizontal movement with resultant crushing; on the other hand, channeling tends to occur along the walls owing to shrinkage of the stone in burning added to the initial greater void space in this region. Form *B*, with a maximum taper of 1 : 30, is not usual, since it is unnecessary to aid the fall of charge in other than exceptional cases, and it accentuates wall channeling and horizontal movement as compared with the vertical wall. Forms *C* and *D* have been used[a] extensively in mixed-feed kilns (*post*) since they have the double advantage of decreasing the size of feed and discharge arrangements, and of spreading out the charge in the firing zone; the converging bottom aggravates any tendency to stick, however. Form *E* is used in gas firing with the idea of decreasing the horizontal distance to which the fuel, introduced at the throat, must penetrate; and with furnace firing, in order to converge the stone and hot gases and thus insure even heating in the hot zone. Form *F*, with many modifications in the way of bulge and constriction, has been used for a variety of purposes, *e.g.*, in the Aalborg type, to help in the introduction of solid fuel through the wall under the constriction; in top-fed mixed-feed types, to decrease segregation; in furnace-fired types, for convergence of the opposed streams, as in Form *E;* and generally, in order to cause horizontal rearrangement of the charge.

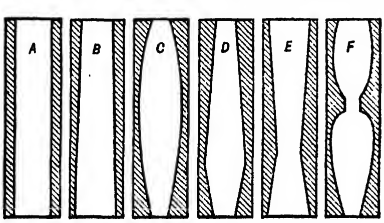

FIG. 37. Longitudinal sections of shaft kilns (*after Knibbs*).

Firing. Both solid and vaporous fuels are used, burned either in the charge or in an external furnace. With external furnaces and/or vaporous fuels the vapors enter two or more ports through the shaft walls at the bottom of the burning zone; their ability to penetrate horizontally and evenly into the

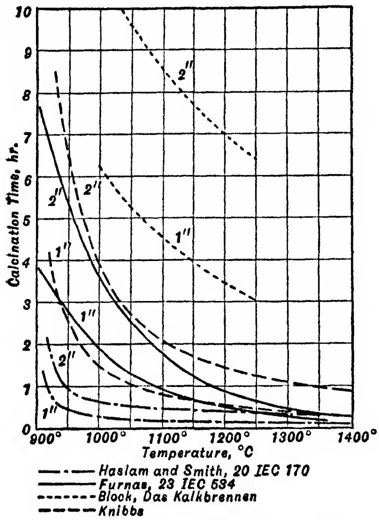

FIG. 38. Rate of calcination, 1- and 2-in. limestone.

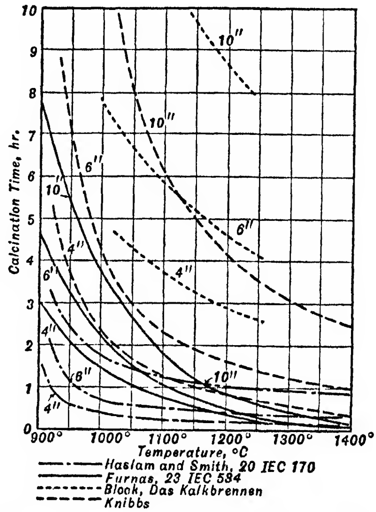

FIG. 39. Rate of calcination, 4-, 6-, and 10-in. limestone.

mass of stone limits the horizontal dimensions of the kiln. Practice has shown that the maximum distance of reasonably even penetration into 6-in. stone of short size range is about 4 1/2 ft. (*10 CLM 59*); the distance decreases rapidly with longer-range stone and for smaller sizes. To obviate this difficulty, solid fuel is frequently charged admixed with the stone (or if charged separately, admixes in the downward travel). Kilns thus operated are described as MIXED-FEED types. The disadvantage of mixed-feed firing is that all of the ash is mixed with the lime, increasing the tendency to overburning, requiring to be screened out of the product, and inevitably increasing its impurity content.

Dimensions of shaft. The shaft consists of three roughly defined zones: (1) a preheating zone, extending downward from the charging level to the height at which the stone first reaches dissociation temperature; (2) a burning zone, comprising the space in which active dissociation occurs and extending vertically from the bottom of the preheating zone to the bottom of the zone of active combustion, or of hot gas introduction; (3) a cooling zone, extending from the bottom of the burning zone to the point of discharge. The preheating zone should have sufficient volume to allow transfer to the stone of most of the heat of the gas leaving the burning zone; the burning zone must have sufficient volume to hold the stone until calcination is complete; and the cooling zone should be large enough to hold the lime until, by radiation and conduction, its temperature has been reduced to a point that permits final handling without further cooling.

FIG. 40. Rate of calcination *vs.* temperature and thickness of lump; high-calcium limestone at 760 mm. CO_2.

Cross-section. The smaller horizontal dimension in the burning zone of a furnace- or vapor-fired kiln taking coarse feed should not exceed 9 ft.; mixed-feed types may be larger, but usually are not. The largest minimum horizontal dimension in the burning zone of 233 shaft kilns reported on by Porter (*loc. cit.*) was 9 ft. 8 in. for a circular kiln; the smallest minimum was 4 ft. 6 in.; average diameter of 76 CIRCULAR KILNS was 7.2 ft. Of 117 ELLIPTICAL KILNS, the maximum length was 16 ft., the maximum width 7 1/2 ft.; corresponding minima were 5 1/2 and 4 1/2 ft.; averages were 6.8 and 5 ft.

Height of burning zone, taken with cross-section, determines the time-factor for a given production. For estimation, short-range compact limestone (sp. gr. 2.7) may be taken to have a struck-volume density of 95 lb. per cu. ft.; long-range stone will run 100 lb. or more. Burning time at usual firing temperatures for stone of various sizes, as compiled by Knibbs (*loc. cit.*), is given in Figs. 38 and 39; similar data based on Conley's equation (p. 52) are shown in Fig. 40. On the basis of these data, volume may be calculated.

Proportionate heights of the three zones (assuming substantially straight sides) depend upon the quantities of heat to be transferred and the relative rates of transfer. Knibbs (*loc. cit.*) estimates quantities in Table 13.

Table 13. Heat transfer in zones of a shaft kiln *a*

Zone	Temp. rise, °C.	×	Sp. ht.	×	Conversion factor	+	Heat of dissociation	=	B.t.u. per lb. of lime
Preheating.........	900		0.27		3.2		.....		778
Burning...........	200		0.22		1.8		1,250		1,329
Cooling..	1,100		0.21		1.8		.....		415

a Assuming a stone temperature of 1,100° C. and the cycle as from 0° to 0° C.

Transfer rates depend on the temperature differentials between stone and gases, concerning which little or nothing is known except at the top of the kiln. Hence the proportionate heights, as estimated from heat quantities in the above table, must be considered wholly approximate. Fig. 41, after Knibbs, represents another approach to the problem. Maximum total height of the 233 kilns reported on by Porter was 60 ft.; minimum, 5 ft.; average, 20.6. Calcination temperature is usually reached about 8 ft. above the grates (*IC 6884*). Knibbs summarizes the factors influencing kiln height as follows: In a tall kiln, heat transfer and, consequently, heating efficiency are better; solid falls more evenly, feed distributes better, and even discharge from the full cross-section is more readily effected; gas is more readily distributed and upward flow is more uniform. In the short wide kiln, power consumption for elevation of feed (and fuel) and for draft is less; there is less breakage; initial cost of kiln and maintenance (relining) are lower; radiation losses are lower; and the percentage of peripheral voids is less. (For detailed discussion of the incidence of these factors see *10 CLM 139.*) The modern trend is toward high kilns.

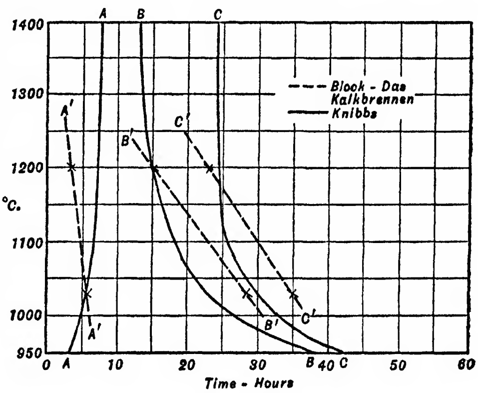

FIG. 41. Times for preheating, burning, and cooling; 6-in. stone.

Capacity of modern shaft kilns on 6-in. stone is about 1 ton of CaO per sq. ft. of cross-section per 24 hr. with 3-in. draft (Azbe, *44 #5 RP 58*). Finer stone can be burned but requires more draft. However, it calcines more quickly because of greater surface, if heat is properly distributed.

At UTAH LIME & STONE Co., Salt Lake City (*45 #1 RP 103*), $^5/_8$~$^3/_{16}$-in. stone is burned in a 14(high)×4 $^1/_2$×7-ft. shaft kiln at the rate of 1 ton of CaO per day per sq. ft. of inside cross-section. Discharge is automatic and continuous. Temperature of exhaust gases is 520° F., and that of discharged lime 135° F.

Shell is usually of steel; brick, stone, and reinforced concrete are also used.

Linings are different in different parts of the kiln, and differ also according to the way in which the kiln is operated. If travel is relatively continuous, the duty of the lining in the PREHEAT ZONE is primarily to resist abrasion, and hard clay brick (paving brick) or fire-clay brick is ordinarily used. Cut stone may be used, but is normally more expensive than brick. Lining in the BURNING ZONE is subject to corrosion by the lime, and to abrasion of the resulting softened surface by the falling charge. Fire-clay refractories are commonly used; quartzite block and high-silica brick have also been used to a considerable extent. High-alumina refractories have been used, but they flux rapidly with lime at temperatures below the overburning temperatures of some limes. THICKNESS is usually 8 to 18 in. COOLING ZONE is lined at the top with the same material as used in the burning zone; below this point the principal requirement is sufficient crushing strength to withstand the weight of the brick above, since it carries the entire weight of this.

Insulation. Heat lost through kiln walls ranges from 5 to 25% of the total heat supplied, according to the amount and character of insulation; the percentage based on the burning zone may run as high as 50 or 60% (*10 CLM 148*). The extent to which insulation is applied depends upon resolution of the economic balance between fuel consumption and liner life. The problem arises only in the burning zone, since there is excess heat in the other zones. Insulation of the burning zone lowers the rate of heat transfer away from the inner surface of the liner, with the result that it is raised to the temperature of relatively rapid reaction with the lime. Many kilns have been run without insulation where fuel was cheap, the liners being run down to the point of failure by crushing. With high fuel costs, however, the trend is toward use of a good refractory lining and good insulation. Usual insulating materials are porous brick (fire clay or infusorial earth), or granular or fibrous fillings such as sand, clinkered ash, broken brick, asbestos, and slag wool; any material should have sufficient crushing resistance to lend support to the lining.

Charging. Kilns may be open or closed at the top, depending upon the draft necessary and upon whether use is to be made of the CO_2 content of the gases. Open-topped kilns are usually built up at the top with some outward flare for a sufficient distance to afford storage for a 24- to 48-hr. supply of rock to tide over short interruptions in supply. Closed-top kilns require provision for relatively gas-tight entry of feed, either by a star-type feeder (Sec. 18, Art. 22) or the like, or by some form of bell feeder (Fig. 42), comprising a conical (or pyramidal) hopper *a*, carried on a steel shell *b* comprising an extension of the kiln shaft; and a heavy conical (or pyramidal) bell *c*, closing the bottom of *b* by either upward or downward movement (as shown), and suitably guided on stem *d* for accurate closure. The bell is usually mechanically operated, but may be counterweighted for manual operation. Flue *e* leads to a stack or an absorption chamber. When stacks are used for draft, they are best made converging extensions of the kiln walls, with provision for quick charging through doors.

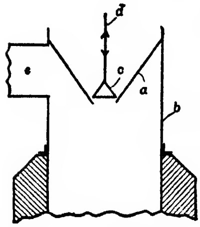

FIG. 42. Diagram of bell feeder for a shaft kiln.

Elevation of rock (and fuel) to the charging floor may be by conveyor, in which case auxiliary storage hoppers are usually necessary, or by cars lifted on vertical hoists to a charging floor, or by inclined or vertical skips discharging directly to the bell hoppers.

Discharge is effected by a variety of means, a number of which, as pictured by Knibbs (*10 CLM 81, 83*), are shown in Fig. 43. Forms *A* to *F*, comprising, in order, an apron conveyor, a revolving table, revolving grates (*C* and *D*), a push grate (*E*), and push feeder

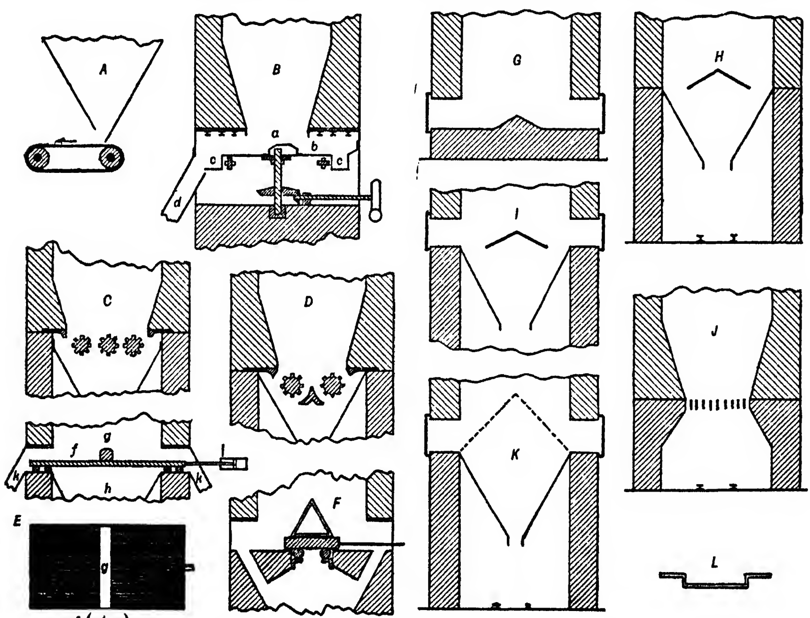

FIG. 43. Forms of discharge arrangements for shaft kilns.

(*F*), are for continuous discharge; forms *G*, *I*, and *J* are for intermittent discharge on small kilns, material being hoed out in *G*, barred into the hopper in *I*, and released by turn or removal of grates in *J*.

Fuels. For discussion of fuels and thermal efficiencies see Vol. II. See also Knibbs, *10 CLM 209, 240, 274, 301; 11 CLM 14;* Hardgrove, *148 A 398;* Green, *148 A 1396;* Porter, *loc. cit.*

Eldred process for firing shaft kilns comprises recirculation of a part of the flue gas (usually drawn some distance below the top of stone) through the grate of a furnace-fired kiln. The effect is to cool the grate, partly by heat transfer therefrom to the cooler air, partly by cooling the bottom of the fire

bed by the endothermic reduction of CO_2 in the return gas to CO. This burns again above the bed, serving to lengthen the flame. Steam fed under the grate acts similarly, being reduced to H_2 and CO; the amount required ranges from 0.3 to 0.6 lb. per lb. of coal. The effect of the longer flame is also to reduce time-factor in the kiln slightly (*TP 416 USBM*).

Rotary kilns, originally adopted from cement practice for burning the spalls (fines) produced in breaking lump lime for shaft kilns, are now used generally for most large daily production of stone lime, and for all production of shell lime and lime from sludges.

Construction is the same, in general, as that for cement kilns (Sec. 3A, Fig. 7), differing therefrom primarily in that provision must be made for supplying heat at the maximum level for a longer time in the lime kiln. This provision normally comprises an enlarged section of relatively short length in the region of maximum flame intensity near the discharge end. SIZES range in general from 5 or 6 × 100 ft. to 7 or 8 × 400 to 425 ft. inside. SLOPE is normally from 1/2 to 3/4 i.p.f. SPEED is best made variable; the usual range is from 3/4 to 3 m.p.r. FIRING, always from the discharge end, is by gas, oil, or powdered solid fuel. RECUPERATION from hot lime is commonly practiced in large kilns. Attempts at recuperation from kiln gases have been made, but have proved unsatisfactory except by outside preheating and in waste-heat boilers. Even in such cases, the saving after amortization of the additional equipment is small.

Operation

Operation of a kiln involves a balance of time, temperature, and heat distribution.

Time is controlled in a vertical kiln by rate of withdrawal; in a rotary, once the slope is fixed, by the speed of revolution. An empirical relation between kiln dimensions and travel for a rotary is (*TP 384 USBM*)

$$t = 1.77Fl\sqrt{\theta}/pdn$$

in which t = time in kiln, min.; l = length, ft.; p = slope, degrees; d = inside diameter, ft.; n = r.p.m.; θ = angle of repose, dry, in degrees; and F is a factor dependent upon the longitudinal configuration of the interior surface. For a kiln of uniform cross-section, $F = 1$. Values of F for three different conditions of restriction of cross-section are given in the following equations:

Constriction higher than uniform surface of bed:

$$F = e^{[(0.12l/d' - 3.86)\log 2.5\,v_f/nv_0 + e^{2.3-0.32l/d'} - 1]h/(d^\circ - 2h)}$$

where e is the Naperian base, v_0 = volume of kiln, v_f = volume of feed per hr., h = height of constriction, d' = diameter of constricted portion, and d° = diameter of kiln, units of volume and length respectively being chosen the same.

Constriction at discharge end and lower than bed surface:

$$1/F = 2.5v_f(0.34 - 0.64d^\circ/d')/nv_o + 1.16$$

Constriction not at discharge end and lower than bed surface:

$$F = [d^\circ/d' - (0.8 - 0.3l/d^\circ)]/(0.3l/d^\circ + 0.195)$$

For a kiln with an expanded portion, calculate separately for the two sections.

Time necessary is determined, for any given temperature, by the character and size of stone, and the CO_2 content of the kiln gases, as has already been discussed; also by the effect of the movement of the stone on the layer of lime surrounding the unburned core. The rotary kiln rubs off this lime layer, to a certain extent at least, as it forms. To that extent, therefore, it reduces the CO_2 pressure at the reaction surface and decreases the temperature that must be maintained on the lime surface to drive heat through to the core at a rate economical from the standpoint of equipment and labor. A time-factor of 1 hr. minimum in the burning zone has been found sufficient with whole oystershell, and yet shorter time for <1-in. crushed shell.

Size of stone is important from a number of standpoints. In a SHAFT KILN it determines the resistance to gas flow and consequently the uniformity of heating and the energy that must be expended in producing draft. The larger the stone the longer it must be exposed to heat for complete burning, and the greater the temperature differential that must be maintained to drive heat from the lime surface to the core surface. If the lump is too large, surface temperatures must be so high that the surface of the lump overburns while there is still unburned core. Usual maximum is 6-in. thickness. Long-range feeds have less interstitial volume than short range, and hold less hot gas (and less heat) at a time than short range. They also offer more resistance to gas flow. Fine short-range feeds have smaller and more tortuous interparticle passages than coarse, and so increase resistance to gas flow. In general, 2 1/2 to 3 in. is the minimum particle thickness for shaft

kilns. If long-range feeds are to be burned in one shaft kiln, it is better to size and either run on one short-range size at a time, or charge the different sizes in layers.

ROTARY KILNS are limited to finer feeds than shaft kilns both because they are not adapted to afford the necessary time factor for large lumps, and because the lumps will not stand the battering of coarse material. Usual maximum for stone is 1 1/2- or 2-in. square-mesh, corresponding to 0.9- to 1.2-in. thickness; usual minimum is 1/4-in. square-mesh. Fine chemical sludges are also burned. Normally the sand sizes from raw stone are not burned, both because of concentration of impurities in these sizes, and because of the long size ranges involved (*e.g.*, 1/4-in.~100- or 200-m. = 43 or 86 : 1), but if there is enough of this fine material to justify shortening the range and burning the sizes separately, or if the entire feed is fine (*e.g.*, coral sand or shell marl), then burning is readily possible. Feeds of long size range in a rotary tend to segregate, with the fines concentrated in the center and shielded from all means of heat supply. As a result the coarse material may come through overburned while the fine still contains core (as much as 20 to 25%). Stone 2~1/4-in. has been sized into as many as six short-range grades to eliminate overburning. Even this is not always successful, since some stones shatter when suddenly introduced into the hot exit gases (*33 #12 PQ 43*).

Temperature in shaft kilns has been discussed (p. 52). In rotary kilns, temperature is under much more rapid and complete control of the operator. Heat transfer in the rotary is effected by direct radiation from the flame, by radiation from the exposed wall, by conduction from the gas, and by conduction from the buried wall. The principal heat supply in the burning zone is the radiant energy from the flame. This is subject to ready variation both in intensity and extent along the kiln. Dust shields much of the preheating zone from the flame; hence here the major supply is the gas, that part of its heat content taken up by the lining being given back, in part, by radiation and direct conduction.

Actual temperature measurements in a rotary burning zone are difficult and uncertain. Usual estimates of gas temperatures in this region range from 1,400° to 1,500° C. (*32 IEC 972*); 1,250° C. has been found satisfactory for 1 1/4-in. spalls, and yet lower temperatures for shell in long kilns (*PC*). Temperatures of exit gases (more easily and accurately measured) are 650° to 750° C. in long kilns without recuperators; much higher in short kilns, because of the necessity for a higher temperature gradient to effect the necessary preheat in the short time available.

Gas velocity. Heat transfer for a given gas temperature is higher the greater the gas velocity, both because of thinning of the stationary (or slow-moving) gas layer at the solid surface, and because of increase in the CO_2 concentration gradient. Consequently lower temperatures can be carried, and less overburning will occur. On the other side, high gas velocity requires either increase in gas volume above that resulting simply from combustion, decrease in cross-section of the gas stream in the kiln, or increase in draft differential.

Design of kiln involves primarily consideration of the size and purity of the lime to be produced; the tonnage to be treated; the character of the feed; the available fuel; and whether CO_2 is to be recovered. LUMP LIME can be produced only in shaft kilns. HIGH-PURITY LIME requires gas (or oil) firing. High daily tonnage requires either a plurality of shaft kilns or a rotary, with first cost and operating cost per ton of product so much in favor of the rotary that it must be selected, unless lump lime is demanded. If the available feed is fine, or, if coarse, it disintegrates under burden, a rotary must be used. All fuels are adaptable to either type of kiln; and high concentrations of CO_2 can be attained in the exit gases with either type, although the design and operation necessary for shaft kilns are better known and consequently this type has been favored for CO_2 recovery until recently. Advocates of rotary kilns list as outstanding advantages: (*a*) ready control of draft, (*b*) steady temperature of exit gas, (*c*) ready control of lengths of temperature zones, (*d*) control of secondary air, (*e*) possibility of control of temperature according to size of feed, (*f*) more complete burning (0.25% CO_2 in run-of-kiln product), (*g*) material decrease in quarry waste and quarry labor, much more than offsetting the cost of mechanical crushing, washing, and sizing for rotary burning, (*h*) attendance for a shaft kiln is one man per 1 or 2 kilns (8 to 25 tons of lime per day each); one man can attend 2 or 3 short rotary kilns or 1 or 2 long kilns with daily tonnages of 175 to 400 each. Meade (*19 IEC 598*) cites a shaft-kiln operation with 6 kilns where labor was 2.2 man-hr. per ton, and a rotary operation requiring 0.6 man-hr. per ton.

The factors entering into the design for shaft kilns, in so far as they are generally known, have already been considered. For greater detail see Knibbs, *10, 11 CLM*, at various pages; also catalogues of the manufacturers of the various equipment.

Choice of rotary kiln. Mechanical features are largely standardized in the light of experience with cement kilns, and do not differ greatly, and certainly not importantly,

as between different reliable manufacturers. The important choices to be made by the lime engineer are as to over-all length and diameter; length and diameter of enlarged section; firing means; extent and kind of heat economizing; and the preparation and handling of feed and products.

Short kiln *vs.* long kiln. A short kiln must be run at a relatively high temperature throughout in order to burn completely in the relatively short time that it affords. It follows that the feed must be of very short range in order to prevent over- and underburning; that it must be relatively fine because of the high temperature gradient from lime surface to reacting surface that is necessary to finish large pieces in a short time; and it must be of high purity, because low-purity feed slags excessively under high temperatures. The requisite high flame temperatures demand excess of fuel, and high exit-gas temperatures follow. If CO_2 is to be recovered, concentration is low because of incomplete combustion. Unless economizers are installed, the saving in first cost of kiln is largely consumed.

A long kiln COSTS installed about $400 per ft. of length (1938) as against about $350 for a short kiln (Cliffe, *33 #12 PQ 43*). Daily kiln CAPACITY of short kilns ranges from 0.3 to 0.9 tons of lime per ft. of length for 5- to 8-ft. kilns, depending upon the diameter, and varies roughly as the square of the diameter for kilns of the same length; long kilns produce up to 1.0 ton per ft. of length. FUEL CONSUMPTION, according to Cliffe, averages about 9,300,000 B.t.u. per ton of lime (with producer gas) for the short kiln *vs.* 8,000,000 B.t.u. in the long kiln, but he reports consumption as low as 320 lb. of coal per ton of lime (±4,200,000 B.t.u. per ton); and a long kiln burning shell and recovering CO_2 is reported (*PC*) to require only 2,400,000 B.t.u. per ton with powdered-coal firing and fuel economizing. Cliffe estimates MAINTENANCE, primarily liner repair and renewal, as 15¢ and 30¢ per ton respectively, the higher cost of the long kiln being due to the more difficult handling. Operating labor is cheaper on the large units, since it depends rather on the number of kilns than upon the tonnage running.

Proponents of the long kiln claim as its advantages that fuel may be burned completely with little or no excess air because of the large combustion space and long time available; this is particularly important when CO_2 recovery is practiced. They also credit the kiln with better fuel economy, as above; lower flame temperatures due to more thorough preheat, and to more surface abrasion, which results in a thinner lime shell through which heat must be driven; less cleaning of feed; ability to handle coarser feed; little or no recarbonation; and a generally more rugged installation. Distribution of reaction in a long kiln, in so far as it can be deduced from samples taken during a short bring-down and after cooling, is shown in Table 14.

Coolers are usually of rotary or Unax type (Sec. 3*A*, Art. 4). Lime can be cooled to about 450° F. in the best types (*42 #8 RP 72*).

CO_2 recovery imposes the necessity for close operating control, if CO_2 concentration in the gas is to be kept at a maximum. The fuel must be completely burned and there must be a minimum of excess air. This requires uniform feeding (and in shaft kilns, uniform withdrawal of lime); close proportioning of fuel to the duty, with regular feed of fuel and the requisite minimum quantity of air for complete combustion; thorough admixture of air with fuel in the hot zone; and gas tightness throughout. Additionally there should be provision for maximum heat exchange between raw feed and exit gas, and between entering air and discharging lime, since both make for high fuel efficiency and consequent reduced ratio of N to CO_2 in exit gases. Insulation, despite its bad effect on the lining, is important from the same standpoint.

Burning of shell is economically impossible in present-day shaft kilns. On the other hand, the low ratio of thickness to length and width favors the short time-factor of the rotary, and the shape of

whole shell (and roughness of oystershell) makes for high repose angles and minimum segregation. Crushing and thorough washing are necessary when short kilns are used.

Thermal efficiency of a kiln. Azbe (*46 #5 RP 62*) presents Fig. 44 as a method of picturizing the distribution of heat consumption in a kiln, and therefrom a concept of efficiency. Loss by reason of the latent heat of water formed by combustion of hydrogen in the fuel is relatively high in gaseous fuels, low in coke, and intermediate with oil. This heat never plays any part in the kiln functions and is, therefore, pictured as leaving the heat stream before this enters the kiln. For the same reason heat in unburned solid fuel, or that which leaves the kiln in CO, is branched off outside. The two main branches of the pictured stream within the kiln represent heat at an intensity too low to effect calcination (upward) and heat at (or above) calcination temperature. The low-intensity heat in part is utilized in supplying sensible heat to the stone and in part is lost in the stack gases and by radiation from the preheat section. The sensible heat imparted to the stone is, after decomposition, in the decomposition products. That in the CO_2 is returned completely into the heat stream as a part of the gas stream when dissociation occurs in the burning zone. That in the lime is returned or not according to the extent of recuperation in the kiln or cooler. The high-intensity heat goes largely into driving the dissociation reaction. A part goes into the sensible heat of the lime, which has had to be heated above normal dissociation temperature in order to drive heat to the cores. A more or less small part escapes to the preheat zone, according to the type of kiln and the way it is operated. A part is lost as radiation from the burning zone.

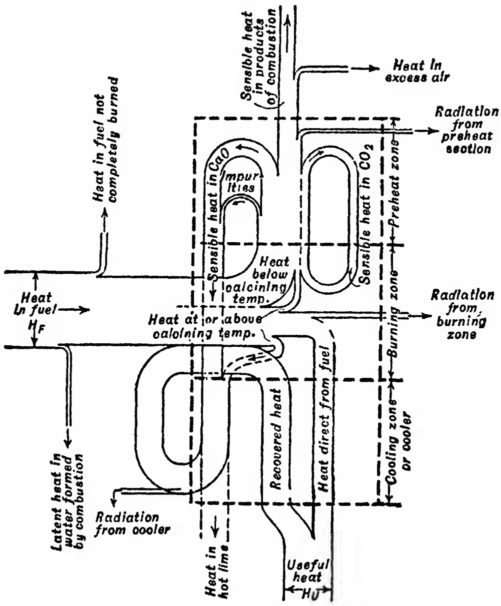

FIG. 44. Efficiency of a lime kiln (*after Azbe*).

Thermal efficiency is variously estimated. The PRACTICAL METHOD is to estimate the quantities of heat required to bring the stone to calcination temperature and to effect the calcination, then divide this by the quantity of heat in the fuel used, *i.e.*, $E = H_U/H_F$. The resulting figures are low—around 50% for average lime : fuel ratios. The KILN SALESMAN'S METHOD is to deduct from the theoretical heat input one or more of the quantities: heat in stack gas, heat gained in calorimetry of the coal by condensation of the water formed by combustion, a minimum radiation loss for an insulated shell (say 5 or 6%), and the heat content of a well-cooled lime; then, calling difference the useful heat input, calculate an efficiency of the order of 75 to 85% (*42 #12 RP 44*).

Fuel requirement may be estimated either from averages of fuel : lime ratios from practice, or by estimating net theoretical fuel demands and applying an efficiency factor. Meade (*loc. cit.*) states that the fuel : lime ratio for a shaft kiln burning a good slack coal is 1 : 2.5 to 4; that for a rotary, producer-gas fired, the ratio is from 1 : 2.5 or 3.5; that the consumption of pulverized coal in a rotary is 20 to 30% less than this; and that fuel requirements are about equal for oil or gas firing. Required heat is the sum of (*a*) that necessary to raise the stone from atmospheric temperature to dissociation temperature (see Fig. 35; sp. ht., Fig. 45); (*b*) the heat of dissociation at this temperature (−38,900 cal. per mol); (*c*) the heat required to raise the

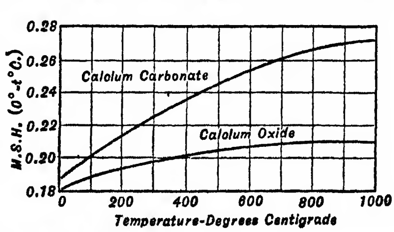

FIG. 45. Mean specific heats of calcium carbonate and calcium oxide (*after Knibbs*).

temperature of the lime from dissociation temperature to some temperature between this and the burning-zone gas temperature (Fig. 45); (*d*) the sensible heat of the water in the feed from atmospheric temperature to boiling point (sp. ht. = 1.0); (*e*) the latent heat of evaporation (966 B.t.u. per lb.); (*f*) the superheat of water to the exit-gas temperature; (*g*) add an allowance for radiation loss (5 to 25%). Deduct from this total (*h*) the heat recovered in cooling the CO_2 evolved from dissociation temperature to exit-gas temperature (sp. ht. = 0.23); and (*i*) the heat returned in cooling the produced lime, when this is done recuperatively. The difference is the total heat required under ideal conditions per unit of weight chosen. Add about 10% for leakage and unavoidable variation in operation. To determine fuel requirement, divide by the thermal efficiency decimal chosen.

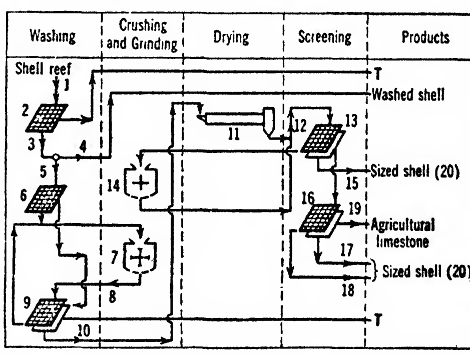
Cost (1927) of plant is given by Meade (*loc. cit.*) as $1,250 to $2,000 per daily ton of lime capacity for a rotary plant, including crushing and limit sizing only, kiln, cooler, drives, and enclosure; corresponding figures for a furnace-fired shaft-kiln plant is given as $1,000 to $1,500 per ton. **Power** required in a rotary plant fired by pulverized coal is estimated by Meade (*23 CME 932*) as 16.5 hp-hr. per ton of lime, and the cost (1920) as $3.25 to $5.40 per ton. Mechanical advances since then, with corresponding decrease in labor requirements, more than kept up with the rise in labor costs up to 1939.

Gulf Crushing Co., Fig. 46.

Location: Morgan City, La.
Products: Rough washed shell for roads, etc.; washed sized shell for chicken grits, etc.; agricultural limestone. See Table 15 for analysis of shell products.

Table 15. Analyses of rough- and clean-washed shell at Gulf Crushing Co.

Item	Percentages	
	Rough-washed	Crushed and clean-washed
SiO_2	2.2 to 4.5	0.050
Fe_2O_3	0.17 to 0.27	0.020
Al_2O_3	0.11 to 0.28	0.010
$CaCO_3$	91.9 to 95.0	98.20
$CaSO_4$	0.43 to 0.51	0.35
$MgCO_3$	0.89 to 1.44	1.21



Legend for Fig. 46:

1. Suction dredge, 24-in. cutter head, 9 to 10 r.p.m., 15-in. Morris pump.
2. 1 @ 9×18-ft. wash trommel, 9-in. shaft, 4-in. fishtail spray, plate with 1 1/2-in. apertures on center spider with 12-in. annulus free, 13 r.p.m., 5/16-in. sq.-m. cloth.
3. 1 @ 24-in. boom conveyor; barge, 25 mi.; derrick clamshell at dock; 1 @ 14 (sq.) × 14-ft. pyramidal hopper with 2 rotary feeders.
4. 1 @ 18-in. belt conveyor; R.R. cars or trucks.

Fig. 46. Gulf Crushing Co.

Summary. One-stage rough screen washing at 1/4-in. for crude washed shell; followed by 2-stage screen washing with intervening crushing for release of interlaminar impurities for ultraclean shell; drying, sizing, and blending grit to specification; dry grinding of fines for agricultural lime.

25. MAGNESITE

Properties. Magnesite (also known as giobertite), $MgCO_3$, may be either compact and AMORPHOUS (cryptocrystalline), or coarsely crystalline. Breunnerite is crystalline magnesite containing more than about 5% isomorphously mixed $FeCO_3$. Hydromagnesite, $3MgCO_3 \cdot Mg(OH)_2 \cdot 3H_2O$, and brucite, $Mg(OH)_2$, are softer and not so heavy as compact magnesite. So-called magnesitic dolomite, produced in Canada, is a mixture of magnesite and dolomite. HARDNESS, 3.5 when pure; SP. GR., about 2.95 for compact, 3.05 for crystalline, and 3.15 for breunnerite. Lightly calcined magnesite (below about 2,730° F.) retains several per cent. CO_2 and absorbs more CO_2 and H_2O from air. Periclase (MgO) is a rare mineral but the name is given also to relatively pure dead-burned magnesite.

Uses. Recently 90% of domestic consumption is dead-burned magnesite for basic furnace linings, chiefly in the open-hearth steel furnace where it is used in grain form for bottoms, as well as in brick and other shapes. Dead-burned magnesite is also added to chrome refractories. Lightly calcined or caustic-calcined magnesite is used for Sorel or allied cements (with $MgCl_2$ or $MgSO_4$) for floors and stucco and in rubber manufacture. It is an important source of magnesium salts and medicinals, for which purpose a little crude magnesite is added. In sulphite pulp-and-paper making, formerly an extensive use, magnesite has been displaced by the cheaper dolomite, which also competes as a source of salts, CO_2, and refractories. Recently MgO made from seawater in California has competed with the mine product even in the cheapest dead-burned refractory grades. For detailed discussion see Seaton, *148 A 11.*

Occurrence. Amorphous magnesite usually occurs as veins or masses in serpentine; crystalline magnesite may occur in large lenticular masses or beds, often associated with dolomite.

Production. Until 1914, Austria-Hungary and Greece supplied the bulk of world production, which reached a maximum of 619,071 metric tons in 1913. Since 1933, total output has fluctuated from 1,000,000 to 1,500,000 tons with U.S.S.R. supplying over 30%, Austria (Germany) around 30%, Manchuria about 15%, and United States over 10%, while Greece, Czechoslovakia, and a group of 10 or 12 other countries each contributed about one-third of the remaining 15%. Domestic production in 1937 was 203,437 short tons, all from California and Washington. Sales comprised 1,952 tons crude, 10,031 tons caustic, and 83,204 tons dead-burned. Imports included 35 tons crude, 2,798 tons caustic, and 56,021 tons dead-burned. In addition there was a small output of brucite in Nevada which went into refractories. The first unit (capacity 15,000 to 25,000 tons annually) of a seawater plant came into production late in the year but no sales of synthetic magnesite were made until 1938.

Selling. Owing to high transportation cost, magnesite is usually calcined before shipment. Small sales of crude f.o.b. California mines have ranged since 1920 from $11 to $15 a short ton. Dead-burned magnesite delivered at Pittsburgh and nearby steel-making centers cost about $20 a ton in 1913, but owing to the tariff and other reasons has generally cost around $35 since 1922, averaging around $19 f.o.b. west-coast mines, although nominally quoted at $25 in 1937. High-grade periclase (94%) is quoted at $65 a ton. Caustic-calcined magnesite has been quoted recently (1941) at $40 for the 95% grade with specially selected varieties even higher, but average sales realization for all caustic-calcined magnesite f.o.b. California shipping points has averaged around $30 since 1929.

Treatment. Careful cobbing and sorting are necessary at most mines. Frequently 2 tons are rejected out of 3 tons mined, yet mechanical concentration was not attempted commercially until 1940. Froth flotation is feasible for some ores (Sec. 12, Art. 52) and sink-float for others (Sec. 11, Table 94).

Bald Eagle mine, Fig. 47 (*148 A 37*).

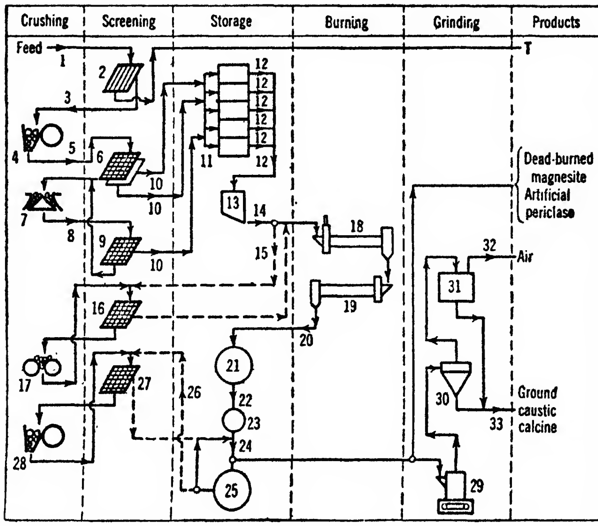
Location: Near Ingomar, Calif.

Ore: Claylike amorphous magnesite as boulders, nodules, and masses in serpentine breccia. Silica, the principal impurity in the magnesite aggregates, occurs in the surface of nodules and in cracks and crevices.

Labor: 3 or 4 men on day shift, 1 on each other shift at BALD EAGLE; 1 man per shift at INGOMAR.

Legend for Fig. 47:

1. By car and aerial tram.
2. Flat grizzly over bin. Hand sorting.
3. 200-ton compartmented bin for ores from different parts of mine; provision for blending discharges.
4. 1 @ 10×20-in. jaw crusher, 2 1/2-in. open setting.
5. Chain-bucket elevator.
6. 1 @ 3×6-ft. 2-deck Symons screen, 3/4-in. and 1/8-in. apertures.
7. Symons cone crusher, 1/2-in. set.
8. Bucket elevator.
9. Symons screen, 1/2-in. aperture.
10. Swinging chutes; automatic samplers to separate small sample bins corresponding to (11).
11. 7-compartment 2,000-ton raw-rock storage.
12. 3 Hardinge constant-weight feeders, electrically interlocked against feed failures; gathering conveyor.
13. 60-ton kiln-feed bin; reciprocating feeder.
14. Bucket elevator.
15. Alternative when kiln feeds down to <10 m. are wanted.



Legend for Fig. 47—Continued:

16. Vibrating screen.
17. Rolls.
18. 1 @ 6(ID)×100-ft. kiln; lining 9 in. thick, 50 ft. of periclase brick, 50 ft. of fire brick; oil firing, manual operation; temperature 2,190° to 3,180° F. according to product being made. A smaller kiln, 2 1/2×20-ft., lined with 4 1/2-in. firebrick, is available for special burns.
19. 1 @ 4×40 ft. rotary cooler, lined with firebrick for 15 ft., steel lifters through balance; enlarged section 5 ft. diameter for 18 in. at discharge end, made of 3/4-in. punched plate (2-in. rd. holes) lined with 3/8-in. punched plate with 3/4-in. holes, containing 2 @ 12-in. steel balls (250 lb. ea.) which break clinker through the 3/4-in. holes.
20. Screw conveyor; bucket elevator; automatic sampler; belt conveyor.
21. 6 steel storage silos, 6,750 cu. ft. ea. = 200 tons calcine or 425 tons periclase.
22. 20 mi. by truck to Ingomar.
23. 10-ton steel receiving hopper.
24. Peck carrier to (25) or to car-loading chutes or
25. 5 steel silos, 150 tons calcine or 250 tons periclase each.
26. Alternative.
27. Vibrating screen.

31. Dust filter.
32. Fan.
33. 3 @ 60-ton silos; packing machines.

FIG. 47. BALD EAGLE MINE.

Summary. Selective mining followed by hand sorting; crushing to <3/4-in.; sizing to 3 grades <3/4-in.; blending and burning to dead-burned magnesia or periclase in rotary kilns; crushing and/or grinding products.

Sea water is a source of magnesia and may, under special circumstances, compete successfully with magnesite or dolomite, despite that the MgO content of typical sea water is about 0.2% (Seaton, *148 A 20*). Recovery depends upon the fact that $Mg(OH)_2$ is very slightly soluble in water while $Ca(OH)_2$ is substantially soluble, wherefore admixture of slaked lime with sea water precipitates $Mg(OH)_2$. The practical essence of the problem comprises (Chesny, *28 IEC 383*) means to insure ready sedimentation and filtration of the gelatinous precipitate of $Mg(OH)_2$, and sufficient prepurification of the sea water and of the lime to insure a precipitate of required purity. A specially favorable case occurs at WESTVACO CHLORINE PRODUCTS CORP., Newark, Calif. (*30 #11 PQ 42*), where the bittern residue from evaporation to produce sodium chloride from sea water contains 10 to 14% of magnesium salts. An outline of the process is shown in Fig. 48. Details of the chemical apparatus and procedure are of primary importance, and should be investigated thoroughly before embarking on what looks like a simple operation with an inexhaustible supply of crude. The plant has competed successfully with magnesite mines as a source of magnesium compounds but has had especially favorable geographical advantages.

Westvaco Chlorine Products Corp., Fig. 48 (*30 #11 PQ 42*).

Location: Newark, Calif.
Crudes: Magnesium bitterns and shell.
Products: Magnesia products; gypsum; $CaCl_2$.

Legend for Fig. 48:

1. Concentrated brine after precipitation of NaCl.
2. 3 Pachuca tanks, used in sequence; while one is filling, a second is agitating and a third cleaning.
3. 2 gypsum thickeners.
4. Dredged from bay with fine sand, clay, and silt.
5. Wash trommel on dredge; washed shell contains about 0.1% clay.
6. Rotary kiln; high-temperature burn possible on account of low silica content of washed shell.
7. Rotary cooler.
8. 1 double-paddle horizontal slaker.
9. 1 single-paddle horizontal slaker.
10. 1 @ 10×36-ft. drum slaker.
11. Thickener to separate $Mg(OH)_2$ sludge from dissolved salts, mostly $CaCl_2$.
12. Countercurrent decantation washing with fresh water, discharging washed $Mg(OH)_2$ from (12*e*).
13. 3 Dorr-type agitators used in sequence for filling, agitation, and settlement and decantation of mixes with silica, clay, and iron oxide for burning slurries.
14. Filter.
15. 1 @ 11- and 7×190-ft. rotary kiln.

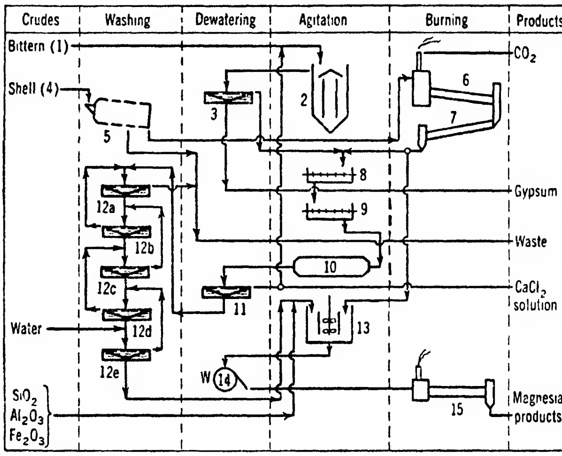

FIG. 48. WESTVACO CHLORINE PRODUCTS CORP.

Summary. Bittern freed of $SO_4^{=}$ by $CaCl_2$; $Mg(OH)_2$ precipitated by $Ca(OH)_2$ slurry, washed, and burned to MgO ± Al_2O_3, SiO_2, Fe_2O_3, etc.

26. MEERSCHAUM

Properties. Meerschaum or sepiolite ($Mg_2Si_3O_8 \cdot 2H_2O$) occurs in compact claylike masses, highly absorbent, generally white, and with uneven fracture. HARDNESS about 2 1/2, SP. GR. about 1.2 (higher if impure), but may float on water when dry. Owing to high absorption it develops a rich color in tobacco pipes.

Uses. Although meerschaum is reported to have been employed as a light-weight building material, as a soap substitute, and also as a remedy for stomach ulcers, it is used almost exclusively in smokers' articles.

Occurrence. Meerschaum occurs at Eskishehir, Bursa Province, Turkey, as nodular lumps, associated with magnesite in residual clays derived from serpentine. Also found in New Mexico as nodules and bedded masses in limestone.

Production. World output, virtually all from Turkey, may have exceeded 10,000 boxes, weighing 30 to 35 kg. each, in 1869, but probably averaged only 7,000 a year in 1914 when war paralyzed the industry of carving pipe bowls and cigar holders, long centered principally in Germany and Austria. Subsequent output has been much smaller. Imports into the United States were worth $102,803 in 1914 but only $2,077 (508 lb.) in 1934 subsequently rising to $12,681 (3,687 lb.) in 1937.

Selling. Market quotations apply to standard-sized cases, but number of pieces per case may range from only 35 to several thousand, according to how large they are. As long as the material is large enough to make pipe bowls, variation in size is not so important as in quality, and for each of the several size groups there are as many as seven grades, ranging in price from $155 to $335 a case. Small pieces sell as low as $30 a case. It would be impossible to translate these quotations to a weight basis, but average foreign market values declared on imports into the United States have ranged in late years from a minimum of $1.36 a pound in 1924 to a maximum of $4.09 in 1934.

Treatment. In Turkey preliminary treatment of hand-sorted meerschaum is confined to removing adhering dirt, drying carefully, and rough polishing. Before carving, it is generally soaked in wax.

At Sapillo Creek, N. Mex., wet tabling produced clean separation from gangue (*99 J 941*) but the concentrate was virtually unsalable, although artificial meerschaum may be made from chips and dust compressed into blocks.

27. MICA

Properties. Muscovite and phlogopite are the micas of commerce. Biotite (black mica) and other varieties (except lithium and vanadium micas) are virtually unsalable. Vermiculite (*q.v.*), an altered mica, preferably should not be classed commercially as mica. Muscovite $H_2KAl_3(SiO_4)_3$ is commonly called WHITE MICA to differentiate it from AMBER MICA, which is phlogopite, $(H, K, Mg, F)_3Mg_3Al(SiO_4)_3$, but except in thin films muscovite is usually greenish, brown, or reddish; RUBY MICA is the best quality of Indian (Madras) muscovite. Muscovite occurs usually in six-sided plates or BOOKS having a perfect basal cleavage. HARDNESS, 2 to 2 1/2; SP. GR. about 2.8. Phlogopite is a trifle heavier, possibly a little softer, and definitely more resistant to heat. The most useful micas can be split, easily and accurately, into transparent films whose thinness is limited virtually only by the dexterity of the operator. Such films are not only impervious to fire, water, acid, or electricity, but also constant in volume under high heat or extreme cold. Mica is readily distinguished from other platy minerals by the flexibility of the sheets, which usually can be wrapped around a pencil without cracking.

Uses. The electrical industry is the principal consumer of sheet mica and splittings. Considerable quantities are used for stove windows, lantern chimneys, furnace peepholes, nonbreakable goggles, and sundry decorative uses. Ground mica is used mainly (80%) in roll roofing; substantial quantities are consumed in making wall paper, paint, and rubber goods; miscellaneous uses include surfacing asphalt shingles, Christmas-tree snow, lubricants, annealing, concrete surfacing, foundry facings, pipeline enamels, plastic specialties. Splittings are cemented into built-up mica, or mica board. ALSIFILM, made from bentonite, is the only promising substitute for electrical mica.

Occurrence. Muscovite is of widespread occurrence in granites and schists, but usually in small plates of no commercial value. Commercial sources are acid pegmatites. Plates 10 ft. across have been found in Indian mines but any sound crystals over about 1 1/2 in. in diameter may yield usable sheets. Biotite also may be found in granite pegmatites, often to the exclusion of muscovite. Phlogopite is restricted to basic pegmatites (pyroxenites), essentially quartz-free and frequently containing apatite, the occurrence being confined to areas underlain by basic batholiths.

Production. In 1937 the total production of uncut sheet, scrap, and by-product mica in the United States rose to 26,043 short tons valued at $639,981, compared with imports totaling 11,339 tons nominally valued at $2,067,599. These figures are misleading because the United States produces normally only 15 to 35% of its requirements of sheet mica larger than about 1 1/2 by 2 in. and only an insignificant part of its requirements of splittings. The bulk of the domestic output is scrap, ground mica schist, and by-product mica, although American mines also produce almost enough punch and circle mica for domestic needs. The principal importation is splittings, of which American manufacturing plants consumed 4,347,435 lb. valued at $1,257,645 in 1937. These films, ordinarily not more than 0.001 in. thick, cannot be produced by machinery and come mostly from British India; Madagascar and Canada (phlogopite) produce only small quantities. Domestic production of sheet mica in 1937 was 1,694,538 lb., but only 381,638 lb. were larger than punch or circle. Imports of sheet mica total less than 1,000,000 lb. yearly; they consist principally of larger sizes. British India ordinarily has supplied about 70% of the world's muscovite, but increasing quantities have come from South America and the U.S.S.R. Phlogopite has been produced commercially only in Canada and Madagascar; the latter also furnishes some muscovite.

Selling. The value of mica depends chiefly upon the size of flat sheets into which it can be split and also upon whether it is clear or stained. It may be marketed as (1) cut or uncut block, (2) sheet, (3) splittings, and (4) wet- or dry-ground mica. In the United States, mica that will not yield flat films over about 1 1/2 in. square, or that is ruled, rumpled, or flawed in any way can be sold only as scrap, its sole use being for making ground mica; in India crystals that will yield films even 1 in. square may be made into splittings. Only sizes that will yield rectangles 1 1/2 by 2 in. or larger can be classed as sheet quality; slightly smaller sizes are classed as punch. Much apparently good, large mica is ruined by rumpling or distortion. Tangle-sheet mica splits imperfectly; ruled mica splits into ribbons across the cleavage planes; and wedge mica splits into films that are thicker at one end than at the other. Spotted or stained mica contains thin scales or streaks of iron oxides or other minerals, and is worth less than clear, transparent mica, even though its usefulness may not be greatly impaired. Clay staining, usually occurring only near outcrops, may render the mica useless even for scrap; the presence of soil between the laminae shows that the books have been opened up slightly by weathering. Air-bells, too, may ruin mica for use as sheets, unless removable by careful splitting.

ASTM designation D351-33T describes six different qualities of muscovite for each size, ranging from CLEAR to BLACK STAINED OR SPOTTED, but the complexity of grading and classifying is indicated by the fact that there are fully 100 distinct products. Small mica miners can scarcely hope to know how to appraise their product and their appraisal would not be accepted by buyers. The product of any mine is mixed and contains many grades (sizes) and classes (qualities) in ever varying propor-

tions. Even if a universally accepted standard did exist with respect to certain grades and classes, there would still be room for wide difference in opinion as to the value of a mixed lot. Actual prices paid for specified sizes in 1937, as reported to the Bureau of Mines by producers, are shown in Table 16.

Table 16. Average value per pound of domestic uncut sheet mica in 1937

	Clear	Stained or spotted		Clear	Stained or spotted
Punch or washer..	$0.054	$0.049	3×4-in.........	$1.219	$1.032
Circle...........	0.104	0.119	3×5-in.........	1.905	1.247
1 1/2×2-in........	0.277	0.209	4×6-in.........	2.841	1.344
2×2-in...........	0.541	0.368	6×8-in.........	4.427	1.162
2×3-in...........	0.766	0.461	8×10-in........	8.097	2.500
3×3-in...........	1.086	0.791			

Generally speaking, Indian ruby mica, grade for grade and class for class, sells for higher prices than other kinds of foreign or domestic mica. Indian splittings bring all the way from about 10¢ to $1.20 a pound and waste or scrap mica is worth all the way from $6 to $20 a short ton, averaging in 1937 $14.08 per short ton, f.o.b. domestic mines. Dry-ground mica in that year sold for around $23 f.o.b. plant, or $30 a ton delivered at consuming points; wet-ground dropped for a time as low as $50 a ton, the lowest price in years. Owing to gradual lowering of the standards of quality, price comparisons over a period of years are virtually valueless. The long-time trend has been upward, with prices for small sizes advancing much more than those of larger sizes. Until 1919, about the only use for No. 6 mica (1 to 2 1/2 sq. in., the smallest size above punch) was for fuse plugs, but now it is used in much larger quantities than all other sizes combined. During the last 2 decades its price has risen almost fivefold, whereas for No. 5, the next larger size, the advance was a little over fourfold and for some of the largest sizes, scarcely double.

Treatment. Sheet mica is prepared by hand; fine mica by crushing, concentrating, and grinding concentrate. Hand preparation requires skilled labor, because the sheet is easily damaged in the process. The steps are, in order: (1) Cobbing and cleaning the crude masses (BOOKS) to remove all external nonmicaceous material; (2) RIFTING, *i.e.*, splitting into sheets that are thin enough to be TRIMMED or cut by hand, usually 0.01 to 0.04 in. thick; (3) trimming to rectangular sheets of the approximate dimensions shown in Table 16, the trimming being done with a sickle-shaped knife (Bengal SICKLE-TRIMMED) which produces beveled, irregular edges, or with a knife, guillotine, shears, or the thumb; (4) grading to size by comparison with a standard template; (5) classification into grades according to quality on the basis of inclusions, color, sheen, flexibility, etc.; (6) splitting with a thin-bladed knife to the desired final thickness to produce SHEET or BLOCK, which must be at least 0.01 in. thick; FILM ranging from 0.001 to 0.009 in. thick, and SPLITTINGS 0.001 in. thick or less. Only a few pounds of splittings can be made per day; cost depends, therefore, on the price of labor, and is estimated (*U. S. Tariff Comm., Rept. 130, Ser. 2*) at 3 or 5 to 15 or 20¢ per lb., according to the country of origin. (See also *IC 6822*.) Machine splitting of small phlogopite has been practiced, and many patents have been issued for machine splitting, but no such commercial operation is reported.

Grinding. Mica is one of the most difficult minerals to grind; even the thinnest flakes are tough, elastic, and too slippery to be grasped and torn by ordinary machines. Strong heating or excessive weathering renders mica easier to grind but ruins it for most uses. Wet-ground mica is worth several times as much as dry-ground, chiefly because of its sheen and general appearance. The edges of dry-ground mica are torn and hackly and even the faces of the flakes may be abraded so that it looks like flour and hence is too dull for decorative purposes, has little slip, and does not mix well with liquids.

Dry-grinding. Most modern plants use some type of hammer or attrition mill, usually a grate-type hammer mill with 1/4-in. or 1/2-in. openings, the discharge from which is sent to multiple-deck vibrating screens that produce the desired sizes. Standard sizes at several plants are 80-, 140-, and <140-m.; at other plants the sizing is on 60-, 80-, and 250-m. screens; some of the smaller plants grind through 20-m. and scalp into two sizes on 100-m.

Wet-grinding is usually accomplished in CHASER MILLS, resembling Chilean mills, except that the wheels and the bottom die ring are of wood. Modern chaser mills are 3(deep)×10-ft., of reinforced concrete with steel-plate wall lining and hardwood blocks set end grain up on the bottom. Wheels are 30 in. diameter, of several layers of hardwood plank, spiked together to a thickness of 20 to 24 in., mounted on a yoke slidable vertically on the drive spindle. They more or less float on the charge, which is turned over by following plows. SPEED is about 20 r.p.m. for a 10-ft. mill; POWER CONSUMPTION 20 hp. A batch is run about 8 hr. in a paste containing about 45% water; temperature must be kept down to prevent burning (loss of sheen). Ground material is sluiced to a shallow settling box (through rough-settling troughs if much sand is present); fines are overflowed to settling tanks (or pressure filters) and coarse settlings shoveled back to the chaser mill. Settlings from fine tanks are dried, reground dry, and bolted through 160-m. silk or 120-m. bronze cloth. At one plant the fine settlings are boiled with live-steam coils for about 20 min., scum is skimmed after standing, the tank is again boiled, allowed to stand 2 hr., and again skimmed; after 30 min. further standing, water is siphoned off, and steam turned into the coils for about 12 hr., when the coils are withdrawn with adhering mica

and stripped over a screw conveyor leading to the bolting screens. Cost of grinding and screening, wet or dry, to fine meshes (*e.g.*, 160 silk) is about $25 per ton. For further detail see *148 A 105*.

Best practice calls for feeding only clean scrap to grinding plants, but sand and some clay can be removed before drying by proper classifying and settling. Micronized mica (1,000- or 3,000-m. limiting) is produced in jet impact machines (Sec. 6, Art. 2).

By-product mica is recovered at clay washers (see Art. 9).

At VICTOR MICA CO. near Spruce Pine (*44 #9 RP 48*), initial recovery of mica is made from sluiced mine rock by rejecting >1-in. by screening, roll grinding the balance through 1/8-in. screen, making a rough mica concentrate on Harz jigs, drying, making a suction-screen separation at 8-m. and 14-m. and air-table separation on 8~14-m. and <14-m. sizes.

28. MINERAL PIGMENTS

Properties. The first requirement of any pigment is pleasing, uniform color, although fine grain size and low oil consumption are likewise important. For linoleum and oilcloth fillers, price is perhaps the chief consideration, due weight being given to ultimate economy in respect of oil consumption as well as cost per ton. For a given type of pigment, the relative value is based upon brightness or intensity of color, and its STRENGTH or staining qualities. Many colored rocks, if used alone, might be suitable for mortar or even wall colors, but commercial pigments must be able to retain their color (CHROMA) after dilution with 10 or usually 20 or more parts by weight of ZnO. Paint pigments are mostly under 1-μ in size. Although ASTM specifications limit the >325-m. content of red and brown iron oxides to 3%, and of ochers to 1%, the bulk density of powdered natural pigments usually ranges from 0.02 to 0.04 gal. per lb., and linseed-oil absorption from 14% for fairly coarsely ground colors to 80% or more for semicolloidal precipitated colors; for American ochers the range is from 35 to slightly over 50%.

The most important earthy colors are the iron compounds, yellow ochers, siennas and red oxides; umbers; and blacks. OCHER is the yellow-to-brown form of limonite mixed with clay; it should contain not less than 17% Fe_2O_3. SIENNA (first found in Siena, Italy) is often described as more of a stain than a pigment; with lower Fe content it grades into ocher and with increasing MnO_2 content, into umber. On dilution ordinary brown-black limonite shows new hues: yellow, green, or gray. RAW UMBERS contain 11 to 23% MnO_2 and 25 to 47% Fe_2O_3; they are greenish to very dark brown and grade into manganese blacks. Powdered coal, manganese ores, graphite, and asphaltum are used as black pigments, especially graphite. MINERAL BLACKS and SLATE BLACKS are carbonaceous shales; often low in tinctorial power; they may be toned up with carbon blacks. TRUE BLACKS, those which on dilution reduce to neutral gray, are made principally from some form of carbon, with or without black iron oxide (magnetite or mill scale). The true carbon blacks are: SOOT BLACKS (carbon black, lampblack, gas black), ANIMAL BLACKS (ivory black, drop black, bone black), and CHARCOAL BLACKS. Fe_3O_4 has a black-bluish tint and is favored in certain composition products because of its high density; it is also used to some extent in paints and as an abrasive. RED OXIDES include strongly tinted ground hematites; DOMESTIC REDS (used chiefly as base pigments to which other red pigments are added) may contain 10 to 60% Fe_2O_3 but PERSIAN or INDIA RED contains 65 to 72% and SPANISH REDS contain up to 90%. VENETIAN REDS, though originally imported from Italy, are now made artificially and are diluted with $CaSO_4$. Natural red clays and earths of various kinds have been used as pigment, but most of the better colors are produced by roasting or synthetically. Green earths (TERRE VERTE, VERONA GREEN, etc.) are chiefly ferromagnesian silicates, rich in chlorite, and are used for cheap lakes or bases for artificial chrome and zinc greens.

Uses. Pigments are employed to give color, opacity, or body to paint, stucco, plaster, mortar, cement, linoleum, oilcloth, rubber, and sundry plastic materials. The borderline between pigments and fillers or extenders is not always clear; however, uncolored clays, barite, whiting, etc., are not usually classed as pigments; probably because they have so much less opacity or HIDING POWER than the manufactured white pigments such as white lead, zinc oxide, lithopone, or titanium whites.

Occurrence. Limonite and ochery earth pigments are found chiefly as replacement or precipitation deposits in fractured zones of quartzites or limestones but occur also in clay and other unconsolidated deposits. Iron oxides are universally distributed and some of the deposits are iron ores or marginal ores.

Production. In the absence of actual statistics for recent years, the annual production of natural pigments in the United States may be roughly estimated as around 50,000 tons worth $2,500,000. Formerly it was much higher in good years, but although the demand for pigments has grown considerably, synthetic pigments have displaced natural pigments to a large extent in the paint and varnish industry. In 1929 the value of the domestic production of all kinds of dry colors and pigments reached a peak of $116,752,604. Substantial quantities of ocher are mined in Georgia for export as well as domestic consumption, and various pigments are produced in Pennsylvania, Virginia, and several other states in fairly substantial amounts. France is the world's largest producer of ocher; Turkey (Cyprus) of umber; and Italy of sienna. These countries as well as Germany, Netherlands, and Great Britain also produce other pigments in fairly large quantities. Spanish, North African, and Persian (Indian) iron ores are the outstanding natural red pigments, and there is more or less local production of earthy pigments in almost every country.

Selling. Lack of accurate color and hue standards has handicapped miners in finding markets. Most paint makers are unwilling to experiment with new materials. Since long-established reputation is so important, most of the business is in the hands of a few large producers, several of whom are consumers also. Smaller producers generally find it easier to market their products through dealers or jobbers. Prices for most natural pigments declined sharply after about 1925 but remained fairly steady at the new lower levels after 1935. American yellow ochers are graded in quality from A to H, worth (1938) 2 1/2 to 1 3/8¢ per lb., respectively, the browner shades being cheaper. American golden ocher ranged from 6 1/2 to 3¢ per lb. for A to C grades. French yellow ochers are mostly around 3¢ per lb. Umbers run higher as do most of the imported red oxides. Italian raw sienna was priced at 12¢ per lb. compared with 4¢ for domestic.

Treatment. The soft, claylike pigments are treated by comparatively simple washing processes such as are used for clay (*e.g.*, rake classifiers, settling tanks, and filters). Shales and cheaper grades of ocher are dry-ground in hammer mills, which may be equipped with throwout devices or may operate in circuit with air separators for removing sand and other hard impurities before they are pulverized and enter the product. Ball mills and various pulverizers are used for the harder materials; for the softer materials roller mills seem to be indicated. Buhr mills, once universal, have been largely abandoned. Wet-ground materials are sized by levigation and dry-ground materials by air separation; formerly everything went through bolting cloth. Steam-heated drum-type driers are preferred for wet-ground ocher; at a Georgia mill thickener underflow is spattered on a 4×10-ft. drum, the spattering device being a 3-in. shaft studded with 3-in. bolts and rotated in the pulp at 200 r.p.m. Other types of driers may darken the product by tending to allow portions of it to be heated too long. For making burnt ochers, red metallic paints, etc., the raw materials are calcined in vertical shaft kilns, rotary furnaces, platform calciners, or floor kilns. All pigments may be toned up by adding aniline dyes or artificial pigments.

29. NITRATES

Properties. Aside from inconsequential amounts of true saltpeter (KNO_3), chiefly as efflorescences in soil and occasional accumulations in caves, the only natural commercial nitrate is CHILE SALTPETER ($NaNO_3$). The crude (CALICHE) is a mixture of clay, sand, stone and a cement of more or less soluble salts ranging in composition from 5 to 30% each of nitrate, chloride, and sulphate of sodium, with minor percentages (0.1 to 5%) of K, Mg, and Ca, chiefly in the slightly soluble double sulphates bloedite (Na_2SO_4, $MgSO_4 \cdot 4H_2O$), glauberite ($Na_2SO_4 \cdot CaSO_4$), or polyhalite ($K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$). Darapskite ($NaNO_3 \cdot Na_2SO_4 \cdot H_2O$) comprises 30% of some deposits; it is relatively insoluble in cold water but breaks down and dissolves at about 130° F. Small amounts of potassium perchlorate, sodium iodate, and some borates are also present. The water-soluble salts comprise 20 to 80% of the caliche. Color ranges from pure white to browns and reds, occasionally yellow, black, or even blue. Nitratine ($NaNO_3$) is highly soluble in water; HARDNESS is about 1 1/2; SP. GR. about 2.2.

Uses. The principal use of sodium nitrate is in fertilizers. Prior to 1914 Chilean nitrate had a monopoly of the world's fertilizer market except for the relatively small output of ammonium sulphate from by-product coke ovens, gas works, etc. As recently as 1920 it was the major source of nitrogen for the manufacture of nitric acid and it is still used as a direct ingredient of explosives. Minor uses are as a flux in metallurgy, in glass making, for curing meat, and to a very minor extent in medicinals. With the commercial development of processes for synthetic ammonia and nitric acid, natural sodium nitrate was rapidly supplanted by the air as a source of industrial nitrogen, and in the fertilizer field it meets competition not only from ammonium sulphate (largely from coal) but from synthetic sodium nitrate and other products resulting from the fixation of air nitrogen, *e.g.*, nitrogen oxides, cyanides, cyanamide, and ammonia. Synthetic nitrates are now made chiefly from ammonia, the necessary H (hydrogen) being furnished as producer gas generated from coal. Some of the minor elements present as impurities in Chilean nitrate are claimed to enhance its value as fertilizer.

Occurrence. The Chilean nitrate fields are in an arid mountain trough paralleling the coast along the lower western slopes of the Andes. The deposits are spotted in an irregular belt 5 to 40 miles wide and about 400 miles long. The workable caliche beds range in thickness from about 1 to 14 ft.; most lie within 1 to 4 ft. of the surface, but overburden may be as much as 25 ft. Similar but noncommercial deposits have been found in Africa, western Mexico, southern Peru, and southwestern United States. Cave deposits, located in the Southern States, were used for making gunpowder in early days. Nitrates of potash and/or soda are often found in the playas or dry lakes in the desert regions in the Southwest, particularly in California and Nevada, but have never been worked profitably.

Production. World output of nitrogen was 300,000 metric tons in 1900, 2,000,000 tons in 1929, and rose to more than 2,500,000 tons in 1937. Since 1931, Chilean nitrate has contributed only about 10% of the total, compared with more than 60% in 1900 and 20 to 35% during the early 20's. In 1928–29 exports of Chilean nitrate were about 3,000,000 metric tons, exceeding all previous records, but prices were relatively low.

Selling. Prices in 1914–18 were $60 to $75 per short ton; thereafter stabilization at $45 per ton f.a.s. Chile was attempted unsuccessfully and by 1934 the price was $18.80. By agreement with the

World Nitrogen Cartel the price of 92% crude nitrate f.o.b. New York City, carloads, was advanced progressively from $24.80 in 1935 to $28.30 during the latter part of 1936 and thereafter.

Specifications for Chilean nitrate are 95.5% $NaNO_3$ min., 2% max. moisture, 1.5% NaCl, 0.75% KCl, and 0.5% borax. It contains 15.5 to 16.2% N. SHANKS-PLANT PRODUCT generally carries about 1.15% KNO_3, 0.7% $Mg(NO_3)_2$, and 0.13% $Ca(NO_3)_2$. Formerly a 91–95% grade for fertilizer use and a 96–97% technical grade for making nitric acid and other industrial uses were offered. GUGGENHEIM-PROCESS NITRATE runs over 98.5% $NaNO_3$; it is in pellets 1/32- to 1/8-in. diameter.

Shipments are made all over the world, leading consumers being the same as for other fertilizer materials. Roughly one-third of the nitrogen needs of the United States is imported in the form of Chilean nitrate.

Treatment. About two-thirds of Chilean nitrate-plant capacity utilizes the old Shanks process and one-third the newer (1927) Guggenheim process. Recovery by the SHANKS PROCESS is approximately 65%; fuel and labor, comprising about 40% each of total cost, are wastefully employed; hence only the richest deposits (>12% $NaNO_3$) can be worked profitably under existing conditions. The GUGGENHEIM PROCESS recovers 85 to 90%; it adapts to nitrate recovery the methods previously employed at CHILE COPPER CO. (Chuquicamata) for soluble copper. By mechanical mining and handling and improvements in leaching and crystallizing technique, it can work caliche containing as little as 8% $NaNO_3$. Output of nitrate per man-year is 167 tons compared with 60 to 70 by Shanks process; output per ton of fuel is 25 to 30 tons compared with 6 to 7; costs are nearly halved.

Both processes utilize the fact that the solubility of $NaNO_3$ increases with rise of temperature, whereas that of NaCl remains substantially constant. The Shanks process leaches with boiling solution (280° F.), which is thereafter cooled to normal temperature (about 50° F.); the Guggenheim process uses warm solution (104° F.) for leaching and then refrigerates it to about 40° F., utilizing heat exchange on the cooling system and power plant for much of the heat input. (See Fig. 49.)

By-products of the nitrate plants include iodine and potassium nitrate, which build up in and are recovered from the mother liquor, and sodium sulphate, which is recovered from the caliche residue from nitrate extraction by leaching with water at 65° F.

Shanks process, used at small plants, leaches <2 1/2-in. jaw-crusher product with boiling mother liquor containing 450 gm. nitrate per li. to pick up about 250 gm. per li. more in 12 to 15 hr.; slimes are then settled out from the hot liquor, and it is run into crystallizing tanks to cool for about 8 days and to deposit the nitrate pick-up. Tailing carries 3 to 8% $NaNO_3$ and crude must contain at least 13% $NaNO_3$ for profitable operation.

Anglo-Chilean Consolidated Nitrate Corp., Fig. 49 (*23 IEC 460; IMR 536; 143 #5 J 50*).

Location: Pedro de Valdivia, Chile.
Capacity: 600,000 tons saltpeter per yr.; 29,000 tons crude per day.
Crude: About 8% $NaNO_3$.
Products: Saltpeter, 98.8% $NaNO_3$; iodine; sodium sulphate; tailing, 1.1 to 1.6% $NaNO_3$.

Legend for Fig. 49:

1. Electric shovels; electric train of 30- to 35-ton cars; car dumpers.

2. Grizzly, 7-in. aperture.

3. 2 @ 60-in. Superior McCully gyratories.

4. 4 @ 7-ft. standard cone crushers.

5. 4 @ 7-ft. short-head cone crushers; product <5/8-in., about 10% >1/2-in.

6. Vibrating screens, 20-m. aperture; undersize is about 20% of total.

7. Screw mixer; 1.8 density, 60° C.

8. Moore filters; a = cake-making period, 1- to 1 1/2-in. cake; b = washing period; final cake contains 3 to 4% $NaNO_3$.

9. 1 of 10 @ 7,500-ton leaching vats in parallel, served by mechanical loading and unloading bridges. The 10 vats proceed from charged to empty according to the cycle shown, as follows: Tepid mother liquor run into (9) to fill interstices and circulating piping.

10. 1 as (9), one stage further advanced; the charge of leach solution is circulated through heat exchanger (20) against Diesel-engine exhaust gas until temperature reaches about 40° C.; solution gradually increases in salt strength.

11. 1 as (9), one stage beyond (10); displacement of strong solution (about 330 to 450 gm. $NaNO_3$ per li. above mother liquor) starting by enriched wash liquor from (12) *via* heat exchanger (21) on the Diesel cooling-water circuit.

12. 1 as (9), one stage beyond (11); displacement proceeding from (13) through exchanger (22) on Diesel cooling-water circuit.

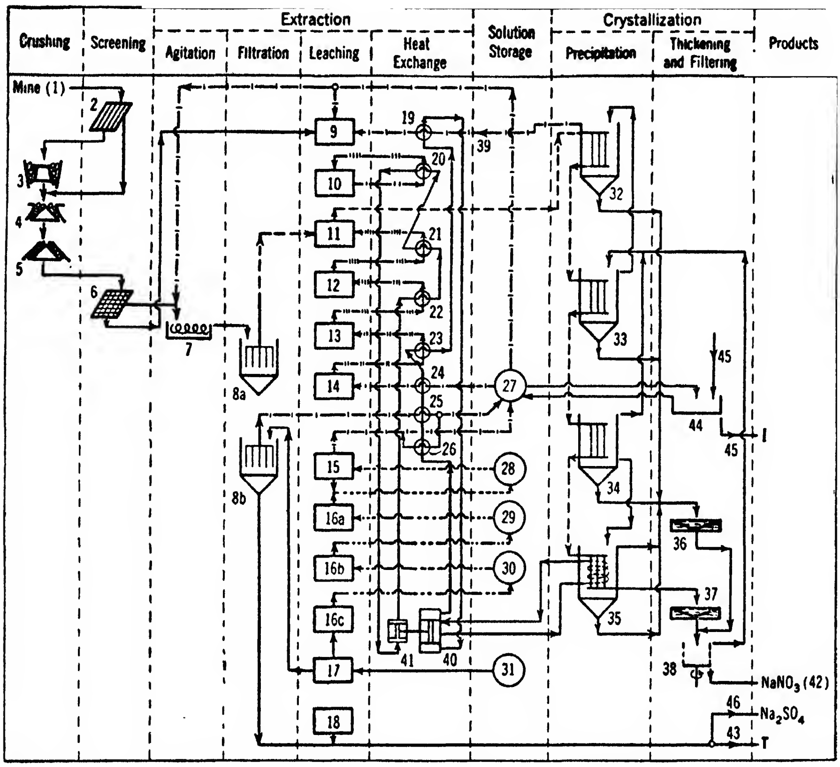
13. 1 as (9), one stage beyond (12); displacement from (13) through (23) on the ammonia-condenser cooling water.

14. 1 as (9), one stage beyond (13); displacement by mother liquor from storage tank (27) through ammonia-condenser exchanger (24). Total contact time with leach solution to end of this stage is about 80 hr.

15. 1 as (9), one stage beyond (14); first drain of mother liquor; displacement by third-wash water from (16*a*) *via* (28) with wash solution weaker than mother liquor recirculated to (28).

16. 1 as (9), one stage beyond (15); three water washes in series with progressively weaker solutions.

17. 1 as (9), one stage beyond (16); final displacement with salt river water from (31).



Legend for Fig. 49—Continued:

18. 1 as (9); unloading; time required, about 8 hr., using 2 @ 5-ton clamshell buckets; vat residue about 1 to 1.5% $NaNO_3$.

19. Indirect heat exchangers against ammonia-condensing cooling water.

20. Indirect gas-vapor heat exchanger against Diesel exhaust gas.

21, 22. Indirect heat exchangers against Diesel cooling water.

23–26. As (19).

27. Mother-liquor storage tanks.

28. Storage tank, first water wash.

29. Storage tank, second water wash

30. Storage tank, third water wash.

31. Storage tank, river water.

32–34. 14 cooling tanks, strong solution in exchange with refrigerated mother liquor; temp. in last tank, 15° C.

35. 6 cooling tanks in exchange with evaporating ammonia; temp. in last tank, 5° C.

36. 2 @ 20-ft. thickeners in parallel.

37. 2 @ 30-ft. thickeners in parallel.

38. 24 @ 48-in. basket centrifuges.

39. Evaporator tower, 35° C.; surge tank.

40. Ammonia compressors; ammonia side.

41. Diesel engines.

42. 98.8% $NaNO_3$.

43. 16-ton dump cars, electric haulage, to tailing pile.

44. Iodine tanks; sodium bisulphite added to reduce iodate.

$$2NaHSO_3 + KIO_3 \rightleftharpoons KI + Na_2SO_4 + H_2SO_4$$

then 1/5 more original iodate solution added, when

$$KIO_3 + 5KI + 3H_2SO_4 \rightleftharpoons 3I_2 + 3K_2SO_4 + 3H_2O$$

45. Filtered, retorted.

46. Water leach of vat residue contains about 125 gm. per li. Na_2SO_4 at 20° C. This is reduced to 45 gm. per li. by refrigeration to 0° C., the salt depositing as decahydrate, which is subsequently dehydrated by heating. Final product 97% pure.

FIG. 49. ANGLO-CHILEAN CONSOLIDATED NITRATE CORP.

Summary. Three-stage open-circuit crushing to 5/8-in.; slimes screened out at 20-m. dry; nitrate extracted from slimes at 60° C. by agitation and filtration; coarse material leached at 40° C.; strong solutions impoverished by selective crystallization of $NaNO_3$ by cooling to 5° C. Solution heated by waste heat from Diesel and refrigerating plants; about 80% of total heat value of fuel oil utilized.

30. PHOSPHATE

Properties. Phosphate rock (PHOSPHORITE) is cryptocrystalline mineral consisting of tricalcium phosphate combined with varying percentages of water, small amounts of $CaCO_3$ (usually under 10%), fluorine, usually 3 to 4%, and organic matter. Iron oxide and alumina are common impurities. The phosphorus content is commercially reported as B.P.L. (bone phosphate of lime, $Ca_3P_2O_8$). Merchantable rock contains 60 to 80% B.P.L., usually from 68 to 77%. Apatite, the crystalline mineral, $Ca_{10}F_2\ (PO_4)_6$, has a SP. GR. of approximately 3.2 but pebble phosphate ordinarily ranges 2 to 3. HARDNESS of apatite is 4.5 to 5.0; pebble phosphate usually 2 to 5. COLOR of pebble is white to gray, brown, or black; apatite usually has a greenish tint.

Uses. Approximately 80% of domestic pebble goes to acidulating plants making superphosphate; an even larger percentage of total production is used for fertilizer. Ferrophosphorus, phosphoric acid, and sundry phosphatic chemicals (including those used in baking powder and in cleansing preparations) are of increasing importance. In 1928 world consumption was 85% for superphosphate, 4% as raw ground rock for direct application to land, 2% for phosphoric acid (calcining and wet process), 5% for metallurgical purposes, and 4% for chemicals, elemental P, and miscellaneous; nearly 95% was ultimately used as fertilizer.

Occurrence. Apatite is a common minor constituent of igneous rocks. Pegmatites containing apatite (usually with other economic minerals) have been exploited in Norway, Ontario, Spain, Russia, and Virginia. In Idaho and adjacent States, British Columbia, and French North Africa the phosphate-rock deposits are of marine origin forming distinct beds, often of high purity, over wide areas. Other sedimentary deposits are residual or formed by disintegration and redistribution of phosphate rock or phosphatic limestones. In Florida, HARD-ROCK PHOSPHATE occurs in irregular fragmentary boulders and gravel embedded in a matrix of sand, clay, and soft phosphate (phosphatic clay); PEBBLE PHOSPHATE, which represents 70% of total U. S. output, comprises pebbles ranging in size from 1 1/2-in. diameter to fine sand, embedded in a matrix of clay and sand and generally overlain by variable thicknesses of overburden. The pebbles form from 10 to 50% of the matrix. In Tennessee, BROWN ROCK residual deposits are leached outcrops of phosphatic limestone; formerly thin beds of BLUE ROCK, similarly formed, were worked. Phosphates resulting from phosphatization of coral limestones by rainwater leaching through guano are mined extensively on various islands in the Pacific and Indian Oceans.

Production. World production was 3 million tons in 1900, to 7 million in 1920, and over 12 million tons in 1937; the United States and French African Colonies each produced about one-third. Pacific Islands produced about one-fourth and the remainder came from 50 or more smaller producing countries. Domestic consumption and exports roughly stabilized in recent years around 2,800,000 tons and 1,000,000 tons respectively. Florida produces 70 to 80% of total domestic output, Tennessee 20 to 30%; small but increasing quantities are mined in Idaho and Montana. The tonnage reserves in the northwestern United States are astronomical figures.

Selling. Lower grades are sold on guarantee of 4% maximum I AND A (Fe_2O_3 plus Al_2O_3); higher grades, 3% max. Size specifications vary; lump rock is preferred for production of ferrophosphorus, elemental phosphorus, and electric-furnace phosphoric acid. Most rock is dried to about 2% moisture before shipment; some, for special purposes, is calcined to remove organic matter. Average prices for Florida pebble phosphate since 1919 have ranged from a maximum of $5.38 per long ton in 1921 to $2.91 in 1933. Florida hard rock dropped from $11.31 per ton in 1920 to $5.75. In 1937, average prices f.o.b. Florida mines were $2.99 for pebble, $5.33 for hard rock, and $3.32 for phosphatic clay or soft rock; the average for Tennessee was $4.05. Prices of various pebble grades for domestic consumption ranged in 1938 from $1.75 to $3.50, value increasing 10 to 15¢ per unit for B.P.L. above 68%. Small quantities of rock carrying 35 to 50% B.P.L. are marketed in Florida or Tennessee for fertilizer filler; equally low grade material may be salable locally for making P.

Treatment formerly consisted in washing in log washers and high-pressure sprays, screening out and discarding all <14- or 20-m. material (largely quartz) to produce finished rock containing about 6% acid insoluble. Now froth or table flotation recovers 80% of the phosphate in washer fines, and over-all recovery has increased from about 50% to about 90%.

American phosphate plants have been unable either to recover slimed phosphate mineral, or granular phosphate in the presence of the ore slimes. Both failures are probably due to the clayey nature of the slimes. Russian phosphate ore composed of apatite in original igneous rock is recovered by flotation, however, in the presence of ore slimes in the usual fashion of floating ground ores (see Fig. 56).

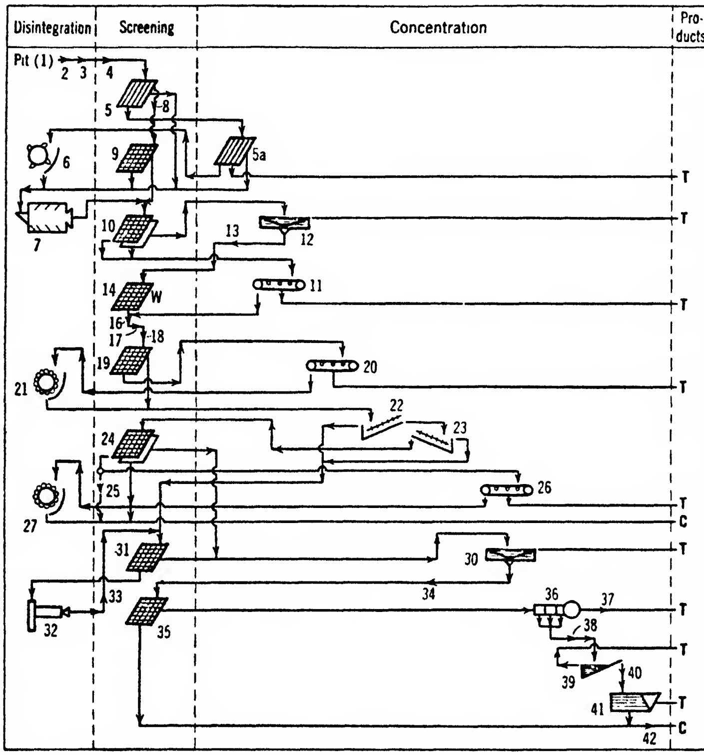
Electrostatic separation is claimed (*142 #3 J 35*) to make 80% concentrate, with recoveries even better than are possible by flotation; if such a claim proved true, the indicated flowsheet (for fines) would be rough concentration by flotation, pushed to make clean tailing and high recovery, retreating concentrate after drying by electrostatic separation.

Hard-rock phosphate plant, Fig. 50 (*148 A 268*).

Location: Northern Florida.

Crude matrix: Phosphatic material ranging from 100-m. sand to 25-ft. boulders together with flint pebbles and boulders and fragmental phosphatic limestone, all in clay. The hard phosphate rock may assay as high as 82% B.P.L.; the sands, particularly the finer, are softer, carry much more I&A and are much lower in B.P.L.

Concentrate: 72 to 81% B.P.L. in sizes from 48-m. to 2 1/2-in.



Legend for Fig. 50:

1. Dipper dredges or draglines. Buckets usually 3-cyd. or less on account of the difficulty in handling larger boulders in the plants; large boulders are mudcapped in the field.

2. 7-cyd. skips on incline.

3. *Field washer*

4. Receiving hopper.

5. Roll grizzly, first part (14 ft.; 6-in. openings), inclined 40° over a transversely divided hopper.

5a. Lower end (5 or 6 ft.) of (5) is horizontal (4-in. openings) over part of lower hopper; it is used for hand-picking coarse waste, washing with 100-lb. water (500 g.p.m.), and regulating feed rate to (6).

6. 24 × 54-in. single-roll crusher, 6-in. set.

7. 1 @ 7 × 14 1/2-ft. A-C blade mill (Sec. 10, Art. 3).

8. Surge bin.

9. Screen feeder, 5/32- to 3/16-in. punched-plate jacket.

10. 1 @ 7 × 14-ft. 2-deck vibrating screen, 1/4 × 1 1/4-in. and 14-m. apertures. Upper deck serves to place coarse above fine on (11).

11. 1 @ 36-in. picking belt.

12. Hydro-bowl classifier.

13. Centrifugal pump.

14. Dewatering screen.

15. As (13).

16. Gondola cars.

40. Bucket elevator.
41. Table flotation.
42. Dewatering drag.

Summary. Plant comprises one or more semiportable field plants making a rough concentrate, which is finished at a central, more permanent mill. Treatment consists of successive rejections of tailing at progressively smaller sizes, with intervening disintegration and comminution of the gradually enriched rough concentrates. Methods of concentration employed are screening, hand picking, log washing, classification, and table flotation. Concentrate is sent wet to a central drying (and calcining) plant.

International Agricultural Corp., Mt. Pleasant plant, Fig. 51 (*142 #1 J 50; 144 #3 J 68*).

Location: Mt. Pleasant, Tenn.
Crude: Clayey.

Legend for Fig. 51:

1. 2-cyd. end-dump cars by steam locomotive; inclined hoist for single cars; sluicing with 125-lb. water.
2. 1 @ 25-ft. McLanahan-Stone log washer, run to just overflow through a 1-in. side grating.
3. 1 as (2).
4. Ty-rock 2-deck screen, 1-in. and 3/8-in. apertures.

25. Rod mill, light rod load, to reduce to <35-m.
26. Bowl-rake classifier.
27. Conditioner, usually agitator boxes of the old M-S type (Sec. 12, Art. 27), two or more in series. Usual reagents are caustic soda, fish-oil fatty acids, fuel oil, and a rosin-oil frother.
28. 4- to 6-cell subaeration machines.
29. 2- to 4-cell subaeration machines.
30. Dewatering drag, water recirculated to (27) and (28).
31. Low-grade phosphate product.
32. Dewatered; dried.

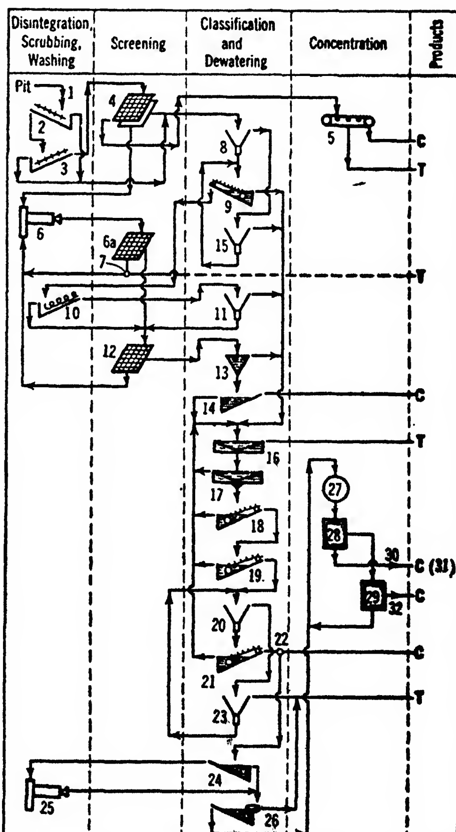

FIG. 51. INTERNATIONAL AGRICULTURAL CORP., Mt. Pleasant plant.

Summary. Disintegration by log washers, sizing of log product at 1-in., and concentration of >1-in. size by hand picking. Reduction of <1-in. material to $^1/_4$-in. and concentration of <$^1/_4$-in. material by classifier washing to recover a $^1/_4$-in.~35-m. concentrate, the separation being dependent on the fact that most of the siliceous impurity is <35-m. Prolonged (and expensive) washing of <35-m. to produce a slime-free 35~200-m. sand for flotation feed, with discard of slime through a thickener and hydrobowl classifier in series. Soap flotation of the resulting product to make a high-grade (72–75% B.P.L.) concentrate and a low-grade siliceous phosphatic concentrate satisfying certain trade demands, *e.g.*, furnace trade.

Southern Phosphate Corp., Fig. 52 (*129 A 295*).

Location: San Gully, Fla.
Crude: Pebble phosphate.

32. 1 @ 6-in. centrifugal pump; 1 @ 4-cell bank of 60-in. agitation-type mixers. Thick pulp acidified with H_2SO_4, agitated to loosen acid-soap coating.
33. 1 @ 25-ft.-bowl quadruplex-rake classifier to remove oleic acid.
34. 4 @ 6-cell 54-in. M-S Air-flow cells with amine and oil. Concentrate grade raised from 72 to + 76% B.P.L.
35. 1 @ 30-ft. thickener.

Fig. 55. International Minerals & Chemical Corp., Peace Valley plant.

Summary. Disintegration by scrubbing and washing, with a single-roll crusher to tear clay balls. Concentration of coarser pebble by sizing; 14~35-m. carefully deslimed, conditioned in a thick pulp and table-floated; <35-m. carefully deslimed, roughed by froth-flotation with fatty-acid collector; rough concentrate cleaned by depressing soap-oil-coated phosphates by an attrition treat with acid and floating quartz in acid pulp with a cationic collector.

Apatite Trust, Fig. 56 (*133 J 429*).

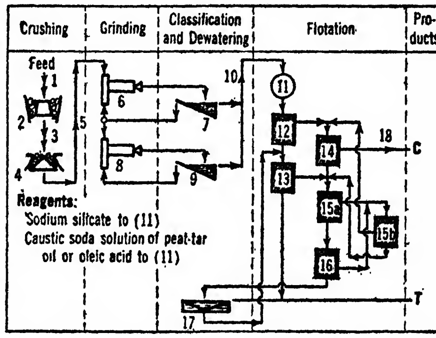
Location: Khibinogorsk, Russia.
Crude: 65 to 70% apatite, balance principally nepheline with a little ilmenite.
Concentrate: 39.5% P_2O_5.
Recovery: 95%.
Ratio of concentration: 1 1/2 : 1.
Distances: Mine to mill, 6 km.

Legend for Fig. 56:

1. 15-ton inverted-V-bottom self-dumping cars; 160-ton bin; 42-in. pan conveyor; <14-in. material.
2. 2 @ No. 20-A Telsmith gyratory crushers, 3-in. open setting.
3. 2 @ 24-in. belt conveyors.
4. 2 @ 5 1/2-ft. standard cone crushers, <1-in. product.
5. 2 @ 24-in. belt conveyors; 1 @ 36-in. belt conveyor with tripper; 1 @ 2,200-ton bin; 18 feeders.

2 sections, each substantially as follows:

6. 2 @ 5×10-ft. rod mills; apatite grinds selectively; 21 r.p.m.
7. 2 @ 6×25-ft. rake classifiers, overflow 33% solids, <80-m.
8. 2 @ 5×10-ft. ball mills; 29 r.p.m.; capacity low because mostly grinding nepheline.
9. 2 as (7).
10. 2 @ 4-in. Wilfley pumps.
11. 1 @ 8×8-ft. conditioning tank.
12. 1 @ 12-cell 24-in. Fahrenwald flotation machine.
13. 1 as (12).
14. 1 as (12).



15. 1 as (12); *a* = cells 9 to 12; *b* = cells 1 to 8.
16. 1 as (12).
17. 1 @ 24-ft. thickener.

Streams joined

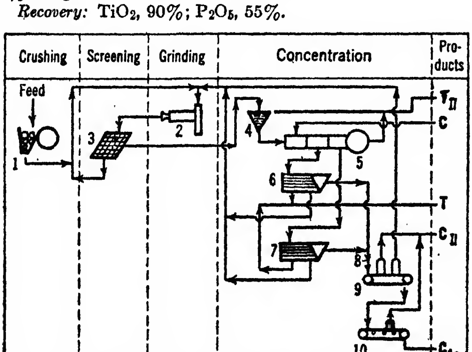
18. 6 @ 750-sq. ft. Genter thickeners, spigot 65 to 70% solids; 6 @ 6-ft. 5-disk filters; 6 @ 6×30-ft. rotary driers (2% moisture).

Fig. 56. Apatite Trust.

Summary. Two-stage open-circuit crushing from <14-in. to <1-in.; 2-stage grinding to 80-m. Rougher-scavenger flotation with one stage of cleaning and reflotation of cleaner middling with intervening de-colloiding.

Southern Mineral Products Corp., Fig. 57.

Location: Piney River, Va.
Ore: Ilmenite and apatite in nelsonite.
Capacity: 100 t.p.d.
Assays: Feed: 18% TiO_2; ilmenite concentrate, 42% TiO_2; apatite concentrate, 40% P_2O_5; tailing, 2% TiO_2.
Recovery: TiO_2, 90%; P_2O_5, 55%.



Legend for Fig. 57:

6. 2 shaking tables.
7. 2 as (6).
8. 2 Akins classifiers (dewatering); drier; 47 tons mixed concentrates.
9. Magnetic separator; micaceous middling.
10. Magnetic separator.

Fig. 57. Southern Mineral Products Corp.

Summary. Crushing and grinding through 35-m. screen; concentration by classification and tabling in series, with separation of table concentrate (mixed) by magnets.

31. POTASH

Properties. In commerce, POTASH is a general term applied to the theoretical equivalent in potassium oxide (K_2O) of all potassium compounds. The principal potash mineral throughout the world is sylvite (KCl). Prior to 1940 it was the only soluble potash mineral mined in the United States (except for minor accessory constituents). Color is milky white to reddish brown, the latter color owing to the presence of a flocculent substance resembling algae in form but of unknown character. LUSTER is vitreous; CLEAVAGE cubical; CRYSTALLIZATION isometric; TASTE, usually described as bitter, is actually about as salty as that of halite, and it produces a cooling effect on the tongue; HARDNESS, 2.2.; SP. GR. 1.98. Other potash minerals are carnallite ($KCl, MgCl_2 \cdot 6H_2O$), langbeinite ($2MgSO_4 \cdot K_2SO_4$), polyhalite ($K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$), and kainite ($MgSO_4 \cdot KCl \cdot 3H_2O$) [KAINITE of commerce is a low-grade fertilizer which may consist of any soluble salt or mixture containing the equivalent of 14 to 20% K_2O].

All the foregoing salts except polyhalite are soluble and more or less important commercially; known reserves of polyhalite are large. Potash is a constituent of many other minerals that are rare or at least not utilized as commercial sources. SILVINITE is a mechanical mixture of sylvite and rock salt or halite (NaCl); in commercial usage the name is applied to various kinds of salts of high potassium content (20 to 42% equivalent K_2O) without regard to composition.

Uses. Over 90% of all potash used in the United States is consumed in agriculture. Nonagricultural uses are, nevertheless, important even when the potassium is merely the ion accompanying a negative ion such as permanganate, bichromate, tartrate, or chlorate. Potassium metal has never had real commercial significance because for almost every purpose it is less efficient than sodium and costs about 50 times as much; domestic consumption is only 50 lb. a year, imported from Germany. Most industrial potassium salts are made from the chloride.

Occurrence. Potassium is widely distributed in feldspar and other rock-forming minerals and dissolved in lake, river, and ocean waters, but workable deposits are confined to salt lakes or beds that have resulted from evaporation, under hot, arid conditions, of saline waters in an arm of the sea or a large salt lake. Such deposits usually consist principally of NaCl but the potassium salts are sometimes selectively concentrated in lenses at various elevations. Some producing potash mines, notably those in southern Germany (Baden), Spain, and southern Poland, are in beds of Tertiary age, but many of the world's best-known deposits, including those of northern Germany, northern Poland, the U.S.S.R., and New Mexico, are of Permian age. The Permian basin in the United States underlies a huge area in Colorado, Kansas, Oklahoma, Texas and New Mexico, but the potash deposits seem to be segregated in a roughly circular area in the southern part, in New Mexico and Texas. Reserves are difficult to estimate, even by closely spaced drilling, owing to irregularity in extent of the potash-rich salts at any given horizon. At Carlsbad, N. Mex., the principal bed now worked is about 10 ft. thick and averages 25% or more K_2O; by lowering the limit for mining to 9%, the thickness of "ore" would be increased to 140 ft.

Production. World production in the 1930's, in terms of K_2O content, consistently exceeded 2,000,000 metric tons yearly, and has risen as high as 2,500,000 tons, of which roughly 60% came from Germany, 15% from France, 10% from the United States, 9% from the U.S.S.R., 4% from Poland, and the remainder principally from Spain and Palestine. In 1937 sales of domestic potash were 270,000 short tons and imports for consumption were 352,300 tons, making apparent consumption around 622,000 tons K_2O.

Selling. Fertilizer manufacturers generally are interested only in the soluble potash (equivalent K_2O) although for certain crops, notably tobacco, sulphate is preferred, especially when accompanied by magnesia. Prices of potassium salts in the United States pre-war were largely controlled by schedules published annually by the New York office of the N. V. Potash Export My., Inc., American sales agent for French and German producers, discount being allowed on orders placed before specified dates for spot shipments and regular deliveries during the following season. Price schedules for the season July 1, 1938, to May 31, 1939, issued in May, 1938, quoted MURIATE (50% K_2O) at 53 1/2¢ per unit of K_2O, 30% MARINE SALT at 58 1/2¢ per unit, 20% KAINITE at $12.75 per ton (bulk), 90% sulphate of potash at $38 per ton in bags, and sulphate of potash-magnesia (48% K_2SO_4) at $25.75 per ton in bags. Discounts were 12% to June 30, 5% to September 30, and net thereafter. These prices are based on seaboard delivery, to which must be added freight to inland consuming points.

Treatment. A variety of processes has been developed with a view to recovering potash salts from feldspar, leucite, and other silicate minerals and rocks; from alunite; and from glauconite—usually by acid leaching, alone or following heat treatment. Volatilization processes also are feasible and NaCl has been added to cement kilns and even iron blast furnace charges to increase the yield of potash in flue dusts which still form a minor source of potash for direct application to the soil. Using porphyry-copper mill tailings in Utah, a process has been developed in the laboratory (*RI 3349*) whereby 90% of the potash is recovered in a 90% KCl product. Immense quantities of such tailings are available, already finely ground, and other necessary raw materials are cheaply availa-

ble locally. The tailings, mixed with salt and coal, are heated to 800° C. and cooled first in a closed container and later in air before leaching with water.

Niter, KNO_3, is obtained from the soil of old village sites in India, and is separated from Chilean sodium nitrate, $NaNO_3$, by fractional crystallization. The leaching of hardwood ashes was so important in the early days that not only K_2CO_3 but even the lye obtained by treating pot ashes with CaO became known as potash. In New Mexico, mine-run salts are taken from headframe bins to crushing plants by belt conveyors and a product sized between 6- and 10-m. is obtained by further screening without hand picking or sorting, and sold as manure salts containing 40 to 48% KCl (equivalent to 25 to 30% K_2O).

High-grade muriate, however, is also made in New Mexico. The UNITED STATES POTASH CO. makes a white, precipitated product containing 99% KCl by solution and crystallization. Somewhat similar methods are employed in Europe, although practice in other countries varies in mechanical detail and in the attention given to fuel economy.

Treatment of the mixed chloride salts depends ultimately on the difference in their variation in solubility with temperature, as shown in Fig. 58. Excluding salt effects, a brine saturated at normal temperatures (say 20° C.) will dissolve considerably more of the potassium salt than of the sodium salt from a mixture of the two, when heated; if then separated from the solid and cooled, it will crystallize only KCl over a considerable temperature range, and, by refrigeration below about 25° C., can be denuded selectively of KCl.

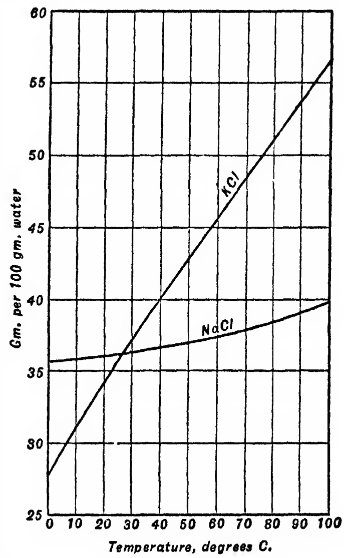

FIG. 58. Solubilities of KCl and NaCl in water.

At Carlsbad, N. Mex., the mixed salts are crushed and then leached in closed dissolvers with almost boiling solution. As this does not dissolve NaCl the latter is sluiced out with cold water before the next charge of crude salts is added for a new cycle. The saturated liquor from the dissolvers is pumped through three vacuum coolers in series. After removing the precipitated KCl in an Oliver filter, the liquor is heated again and sent back to the dissolvers.

Flotation is now used to make the bulk of the preliminary separation of halite from sylvite. Separation is made in a brine saturated with both salts. Very little water is used—no more than can be pumped from the mine itself—which is an advantage in the arid southwest, where the deposits occur. Either mineral may be floated, according to the collector used. See Figs. 59, 60.

At Bonneville, Utah, a mixture of NaCl and KCl obtained by solar evaporation is harvested and then separated by froth flotation.

Potash Co. of America, Fig. 59 (*34 #2 PQ 37; 143 #1 J 38*).

Location: Carlsbad, N. M.
Assays: R.o.m. about 38% KCl; flotation concentrate (cell underflow) averages about 96% KCl.
Recovery: About 86% upward by flotation; upward of 95% overall.

Legend for Fig. 59:

1. 5-ton cars; rotary car dump; pan conveyor.

2. Jeffrey single-roll crusher, 4-in. set. Underground.

3. Skip pocket; semiautomatic Link-Belt counterbalanced-chute feeder; 2 @ 5-ton skips in balance, 1,200 f.p.m.; 1,500-ton headframe bins; belt conveyors to mill.

4. Grizzly.

5. Cone crusher.

6. Jeffrey-Traylor vibrating screen, 10-m. aperture.

7. 4 as (6).

8. 4 A-C smooth rolls.

9. 25 to 30% K_2O.

10. 4 tube mills and 1 @ 6×6-ft. ball mill. Grinding done in brine saturated with sylvite and halite at room temperature. Corrosion is a serious problem with all steel in contact with brines.

11. 5 Akins classifiers.

12. Thickener; overflow to brine system; underflow about 30% solids.

13. M-S subaeration machine, 10 cells; a = first few cells; b = remaining cells. Reagents are Coco-oil or other brine-soluble soap, 0.5 lb. per

Legend for Fig. 59—Continued:

ton added in stages; gas oil, a few tenths of a pound per ton of solid, excess stabilizes a slimy froth; 0.2 lb. per ton of cresol, which is nonfrothing in brine, but acts, with Coco-oil soap, to decrease froth volume, and increase selectivity by making the froth brittle; caustic starch, 0.25 to 0.5 lb. per ton, aids settling and has some beneficial effect on frothing; $PbCl_2$ sufficient (about 0.25 lb. per ton) to maintain a concentration in brine of 2 gm. Pb per liter of brine; *p*H about 7.

14. M-S subaeration machine, 6 cells.
15. M-S subaeration machine, 6 cells.
16. Thickeners.
17. Moore filters; leaves washed in salt brine.
18. Saturated brine.
19. Baker-Perkins continuous centrifuge, 4% moisture in discharge; Ruggles-Coles gas-fired driers.
20. 61.5% K_2O.
21. Hot-water-heated agitators to raise temperature a few degrees and dissolve KCl.
22. Cooled agitators for precipitation of KCl.
23. Drag classifier.
24. Akins classifiers.
25. 2 thickeners.
26. Filter with Monel metal screen, 9% moisture in cake.
27. Two rotary driers, as (19); surge bin; 3 mixers, a small amount of water added; 3 briquet presses making $^1/_2 \times ^3/_4 \times 6$-in. elliptical stick briquets; 24-hr. curing with warm air.
28. Rolls.
29. 2-deck Hum-mer screen.
30. Multiclone collector.

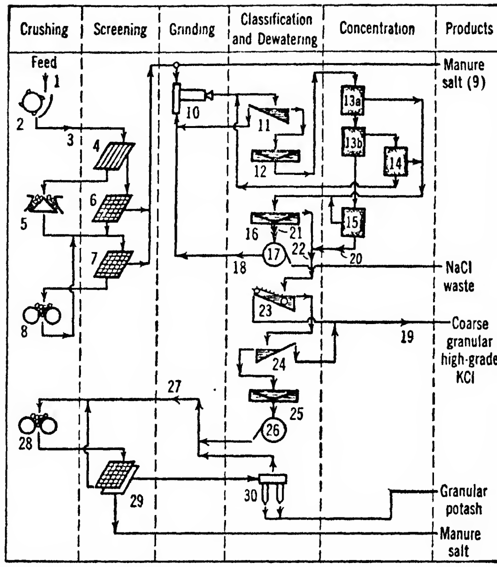

FIG. 59. POTASH CO. OF AMERICA.

Summary. Halite froth-floated from sylvite in saturated halite-sylvite brine with soap.

Union Potash Co., Fig. 60 (*142 #4 J 65*).

Location: Carlsbad, N. Mex.
Capacity: 2,100 t.p.d.
Ores: Sylvite, halite, langbeinite.
Products: Muriate of potash, 60% min. K_2O; 50% muriate; granular muriate, 50% K_2O; washed langbeinite, 22% K_2O (40% K_2SO_4), 18.5% MgO; sulphate of potash, 48 to 50% K_2SO_4.

Legend for Fig. 60:

43. Heated crystallizing vats.

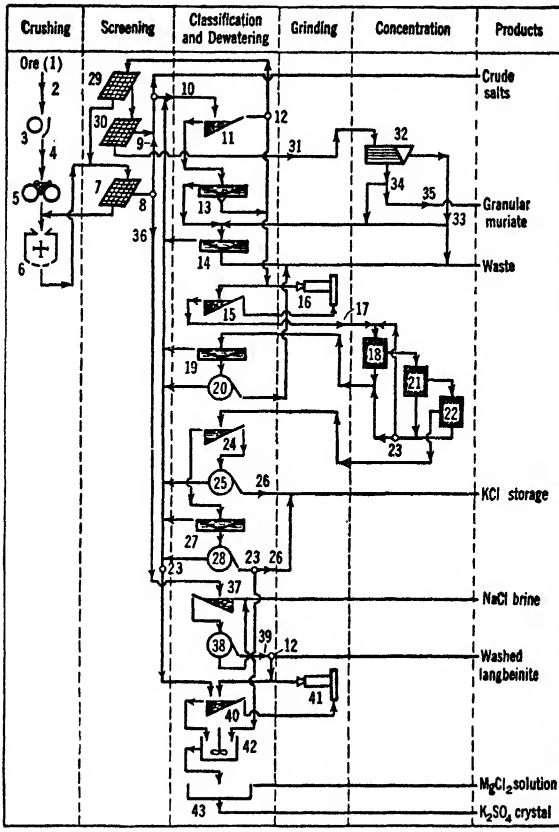

FIG. 60. UNION POTASH CO.

Summary. Crude sylvite and crude langbeinite treated in separate streams. Sylvite floated from halite in saturated sylvite-halite brine, at <35-m. by froth flotation, and at about 8∼22-m. by table flotation. Langbeinite water-washed to remove halite in solution. Langbeinite and sylvite base-exchanged by fractional crystallization to recover potassium sulphate.

32. PUMICE AND PUMICITE

Properties. PUMICE is block and smaller fragments of glassy frothlike lava. In the better grades the vesicles are relatively uniform in size and character, usually elongated slightly. Completely shattered lava, formed of small shards or bubble fragments of volcanic glass, is termed VOLCANIC ASH or, commercially, PUMICITE. Often it looks like closely packed glassy sand, but generally shows sparkling points in bright sunlight. Magnified particles exhibit marked angularity, most of them being clear glass. The copyrighted term SEISMOTITE refers to pumicite; and other names are GEYSERITE and GIBSON GRIT. Commercial pumice and pumicite are siliceous lavas; HARDNESS, 5.5 to 6; SP. GR., about 2.5; lump pumice will float on water, typically weighing about 50 lb. per cu. ft.; color is light gray to white, usually with a silky sheen; it is somewhat brittle, though lumps may be flattened or shaped by rubbing. Pumicite is fine-grained, mostly <200-m. to <325-m., white to light gray in COLOR. A crudely sorted mixture of pumice and ash, used for making building blocks, is known as TRASS.

Uses. Pumicite is used extensively in scouring preparations. Recently both pumice and pumicite have been used increasingly as concrete admixture or aggregate, but in 1937, 68% of domestic sales were for cleansing and scouring compounds, including hand soaps, 2% for other abrasive purposes, 20% for concrete, 5% for acoustical plasters, and 5% for a variety of miscellaneous uses including asphalt filler, road grading, chicken litter, filter aid, building tile, floor-sweeping compounds, and for rock gardens and landscaping. Pumicite has been used to some extent for heat insulation and as a

filler in paints. In concrete, pumicite is not merely an admixture but also a pozzolanic addition (Sec. 3A, Art. 1). The best grades of pulverized imported pumice are used for finishing silverware, watch cases, and other fine metal goods. It is also used as an abrasive or polishing agent in a variety of other industries such as wood finishing, and polishing and beveling plate glass for mirrors. Lump pumice is used for hand rubbing marble and other stone; for rubbing down painted surfaces, automobile bodies, and leather; in lithographing and electroplating; as a toilet article; as a building stone; and heat-insulating brick made of pumice and cement have been manufactured for many years.

Occurrence. Deposits of pumice are always found near centers of volcanic activity. Some deposits are massive and yield large lumps of uncontaminated pumice of uniform structure; others are quite loosely consolidated; still others grade into ordinary hard, dense lava flows. The coarse and fine may be naturally segregated, or the pumice and pumicite may be found in an unsorted mixture. Volcanic ash weathers rather easily to bentonite; hence commercial deposits are generally of recent geologic age, and consequently are most abundant in the United States in the Rocky Mountain and Pacific Coast States; the pumicite deposits in Iowa, Kansas, Nebraska, Oklahoma, and eastern Colorado are wind-blown (*Bul 14 Kan. Geol. Surv.*). The Kansas pumicite deposits, which have been extensively worked, are 16 to 20 ft. thick and lie under about 15 ft. of water-worked sand and a soil overburden. In Italy, high-grade pumice occurs in flat-lying veins or beds accompanied by stony fragments.

Production. Domestic production of pumice and pumicite rose from 15,103 short tons in 1909 to over 70,000 tons in 1936 and 1937. Formerly Nebraska was the only producer but Kansas is now the leading producing state; increasing quantities are being mined in California, Oklahoma, New Mexico, and Oregon. Italy is the leading foreign producer and supplies most of the demand outside of the United States; Germany, New Zealand, Japan, Greece, and probably other countries also have been more or less fairly regular producers; potentially important deposits occur elsewhere. The Italian output, from the island of Lipari, has risen in recent years to 40,000 to 55,000 metric tons a year, of which only 1 or 2% is large first-quality lump (GROSSA), about 10 to 18% small lump (PEZZAME); the remainder is granule (RASSAGLIO) and ash (LAPILLO) grades. About 60 to 70% (4,000 to 6,000 tons a year) of the PEZZAME grade is exported to the United States, chiefly for grinding. The United States also imports up to 200 tons a year of large lump and from 2,000 to 4,000 tons of foreign ground pumice.

Selling. Italian lump and ground pumice are produced in at least 24 different qualities and sizes; the general market grades are: (1) Crude pumice or run-of-mine rock from which only lump pumice has been extracted, (2) lump pumice, ranging from about 1 1/2 to 6 in. across but of any shape, (3) lump pumice, trimmed or cut to shape, and (4) powdered pumice. Specifications are not established; most of the pumicite is powdered by the companies that use it and thus does not come on the market at all. All sizes should be free from grit.

Price of Italian pumice is controlled by competition from other abrasives. For many years lump pumice has ranged from 5 to 7¢ per lb. at New York. The average price of domestic pumice and pumicite, f.o.b. mines, has fluctuated between about $2 and $4.50 per short ton, showing a rising trend due to greater demand and better preparation. Pumice sold for acoustical plaster has been priced around $15 per ton in recent years. Italian-ground pumice ordinarily sells for a little over $25 per short ton, f.o.b. New York, including the $15 duty. This is cheaper than American-ground pumice because pezzame used for the American-ground product costs about $18.50 inclusive of the $2 per ton duty delivered in this country. The quality of the American-ground pumice, however, is superior; it is reported to be as much as three times as efficient an abrasive for certain purposes as pumicite of like grain size. Sharp angular particles are desired for most abrasive uses, but for household cleansers the flattish, striated grains abundant in certain pumicite are preferred because of a more gentle scraping action.

Treatment. In Italy lump pumice generally is smoothed roughly at the mines with files, the best qualities being wrapped in tissue paper and packed in excelsior. Smaller fragments (1/2- to 1 1/2-in.) are bagged. Fines are screened. Material <20-m. is classed as POWDERED PUMICE; that >5-m. as GRINDING ROCK; intermediate sizes are rejected or ground. The roughly screened products are dried and then bolted in hexagonal trommels clothed with wire screens ranging from 35- to 200-m.

At the Long Island City (N. Y.) plant of JAMES H. RHODES Co., pezzame (already freed from obsidian, iron, and other impurities at Lipari) is carefully crushed, screened, dried, and finally bolted through Swiss silk.

Pumicite mined in the Middle West requires little or no crushing. Since it may contain as much as 20% moisture, it goes first to oil-fired rotary driers before passing through a 5-m. revolving screen into air separators. The air-floated product is subsequently mixed with 2% of soap powder for sale as cleanser, while all oversize is rejected. At Fowler, Kans., the material proceeds successively through a pan pulverizer, rotary driers, Hum-mer screens, and a Bates packing machine. The product grades 90% <200-m.; reject from screens is returned to the pan. Further pulverizing is accomplished in the driers, the inner compartments of which are square in section (30-in.).

California Quarries Corp., Mono County, Calif., uses dry concentrating tables to remove sand from light, porous pumice which is then screened to desired sizes, oversize being subjected to graded crushing in rolls. Virtually all sizes from 1/4-in. to <60-m. are produced for concrete work, but the main product is used in acoustic plaster and is 8~30-m.; it is dried and packed in 80-lb. burlap sacks.

33. PYROPHYLLITE

Properties. Pyrophyllite resembles talc (Art. 43) but instead of being a magnesium silicate it is an aluminum silicate, $H_2Al_2\ (SiO_3)_4$; it differs from kaolin in atomic structure and by containing less SiO_2. Hardness is 1.5; sp. gr. 2.8. Compact varieties suitable for carving are included with steatite or pinite under the name agalmatolite.

Uses. Shaped, for tombstones and crayons; ground in ceramics, especially wall tile; as a filler in paper, rubber, battery box spacers, cotton cordage and textiles, roofing, soap, cosmetics, asbestos products, pipe-covering compounds, insecticides and sheet asphalt.

Occurrence. Formed by alteration of tuffs and breccias, chiefly acidic, by heat and reactions associated with granitic intrusions. In North Carolina some lenses are 500 ft. thick and are relatively free from associated minerals. Deposits in Newfoundland and western Canada are mixed with quartz. All deposits grade into sericitic alteration, and contain more or less quartz, sericite, graphite, chlorite, andalusite, and iron minerals which are rejectod so far as possible by selective mining.

Production. No regular production has been reported except in North Carolina, where deposits have been worked in some fashion almost uninterruptedly for 80 years. Statistics have been included with those of talc because one company was responsible for most of the output, but by 1937 there were 4 or 5 companies in the field.

Selling. Ground pyrophyllite, <200-m., is sold in 80- and 100-lb. paper bags, priced in recent years at $7 to $9 per short ton, f.o.b. North Carolina shipping points.

Treatment comprises hand sorting and dry grinding. At Pyrophyllite Talc Products, Glendon, N. C. (built 1937), pyrophyllite, hand-sorted by color, is sent to a Sturtevant crusher and then through a Raymond 3-roller mill in closed circuit with an air classifier. At the new plant of United Feldspar & Minerals Co., Staley, N. C. (*144 #4 J 71*), air-swept 8-ft. Hardinge pebble mills in closed-circuit with 14-ft. Gayco air-separators are used; a series of separate raw-material bins is provided to permit blending for uniformity, and for making special blends. Each order is ground as a separate lot with different settings of the classifier according to size specifications ranging from 80 to 325 *mog.*

34. QUARTZ, SILICA, AND SPECIAL SANDS

Properties and uses. Silica (SiO_2) occurs naturally in macrocrystalline (quartz, tridymite, and cristobalite), microcrystalline (chalcedony), and cryptocrystalline (opal, diatomite) forms. Clear, colorless quartz (rock crystal) is used, when flawless, for optical and radio (piezoelectric) purposes. Smoky quartz or cairngorm (brown in thin section) owes its color to organic matter, removable by heat. Variously colored crystals are gemstones (amethyst, aventurine, citrine, etc.); rose quartz has been carved for ornaments. Crystallization, hexagonal; hardness, 7; sp. gr., 2.65; no cleavage; fracture conchoidal. Any form of silica used in ceramic bodies may be called flint, but true flint is chalcedonic; it is typically light to dark gray in color, extremely hard, and possesses a prominent conchoidal fracture, sp. gr. 2.55 to 2.64. Rounded flint pebbles are used as grinding media, are crushed and graded for use as abrasives, and are ground for potters' use. Carnelian, jasper, and sardonyx are forms of chalcedony. Agate, used for balance and instrument bearings and for ornaments, is semiprecious flint; chert is impure flint, often calcareous. Opaline (cryptocrystalline silica) contains 2 to 13% combined water. Hardness, 5.5 to 6.5; sp. gr., 1.9 to 2.3; luster, resinous to pearly. Precious opal is the most valuable variety. Geyserite (siliceous sinter), deposited near hot springs, is a form of common opal.

In general, the classification of uses by size is more important than chemical composition; uses are summarized below on this basis.

Dimension stone: Rough block, cut stone, rubble, paving blocks, and flagging; furnace block (much so-called mica schist, used for refractory-furnace linings, comes in this category); silex or quartzite tube-mill lining blocks and grinding pebbles or cubes; grindstones, pulpstones, whetstones, scythestones, etc.

Broken or crushed stone: Acid-tower lumps (2- to 8-in.), ferrosilicon manufacture (1- to 3-in.), concrete aggregate, fluxing quartz or stone (or siliceous ores), ganister, rough agate. See Art. 41 for general methods.

Pebbles: Natural flint grinding pebbles (1- to 6-in.) for tube mills (Sec. 5, Art. 6).

Chips and granules: Bitstone or coarse placing sand for potters, roofing granules, stucco and terrazzo; building, paving, and railroad gravel.

Sand: Sand-blasting, glass-grinding, and miscellaneous abrasives, wire-saw and stone-cutting sands, ganister (silica brick), fire or furnace (refractory) sand, glass sand (similar grades used for making sodium silicate and silicon carbide), paving sand, roofing sand, asphaltic sand, bed sand, concrete sand, brick-mortar sand, plastering sand, molding sands, core sands, filter sand, engine sand, and lime-brick sand.

Powder: Plaster and cement filler, asphalt filler, paint and wood filler; potters' flint, rubber filler, miscellaneous filler; silica wash for steel-foundry molds; parting sand; cleaning, polishing, and scouring compounds.

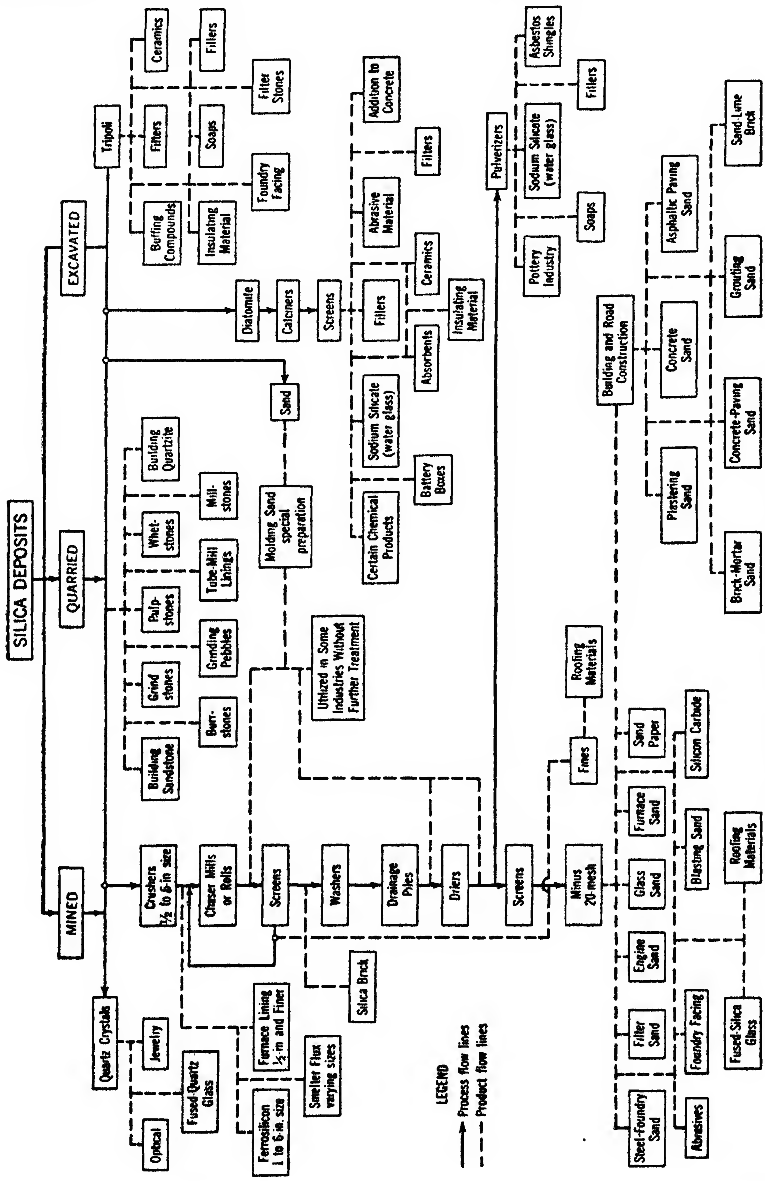

FIG. 61. Preparation and uses of silica (*after Cole, Bul 555, part 1, Can. Dept. Mines 5*).

Occurrence. Quartz is the commonest mineral, next to the feldspar group, yet flawless rock crystal is rare. Enormous crystals are often found in pegmatites, but they are likely to be distorted or strained even when not visibly intergrown; included gases and solid impurities are likely to be visible under the microscope. Double-pointed crystals are found in soft sedimentary rocks but are mostly small. In Brazil the crystals occur in

veins in clay and more or less bedded rocks; they were developed slowly from infiltrated SiO_2 at hot-water temperatures. The yield of crystals is small at most operations. Usually the crystal zone is overlain or intermingled with DOG-TOOTH material comprising partly formed crystals of no value. Gemstones are mostly found in geodes; QUARTZITES are metamorphosed sandstones. FOSSILIZED WOOD is a variety of agate and relatively rare. Flint pebbles are formed in chalk from the siliceous remains of minute marine organisms. Vein quartz is likely to be impure and other sources are more readily worked. Quartz forms the bulk of sands and sandstones.

Production. World supplies of optical and radio crystals have come principally from Brazil; Madagascar has shipped a little, and occasional finds are reported elsewhere. Brazilian exports have ranged as high as 231 metric tons (1935) but about 70% of this was fusing quartz shipped to Japan and worth only 5¢ per kg., whereas crystals which are shipped to the United States and yield a reasonable proportion of usable optical or piezoelectrical material were worth on the average $3.17 per kg. Shipments of really high-grade crystals rose to 15 tons in 1929 but subsequently averaged only 5 tons per year. These large crystals often travel 1,100 mi. on muleback and as far again by train to port. Included in the Brazilian shipments are certain quantities of yellow crystals or false topaz. Madagascar's output was 128 tons in 1929, 1 ton in 1932, and 16 tons in 1933; of this only a small fraction was high-grade quartz. Agate for laboratory mortars and instrument bearings has come mainly from the Brazilian-Uruguayan frontier, fabricated or shaped in Germany.

Domestic production statistics for quartz include those for sand and gravel, sandstone, quartzite, and many other items; separate figures, available for quartz from pegmatites, veins, or quartzite, show production in the United States in 1937 of 13,012 short tons, of which 3,252 tons was sold crude, 5,891 tons was crushed, and 3,869 tons was ground by the producer. Ground sand and sandstone sales in 1937 were 328,156 tons valued at $1,996,528. For figures for other silica products see Arts. 1 and 38.

Selling. In 1937 crude quartz sold or used by producers was valued at $3.10, roughly crushed at $4.18, and ground at $8.09 per ton f.o.b. shipping point. Average sales value for ground sand and sandstone in 1937 was $6.02; nearly half the sales for pottery and other ceramic uses, comprising nearly half of the total, averaged $6.94 per ton. Quartz rock or sand may be priced as low as 50¢ to $1 per ton. Pulverized silica competes with tripoli and other SOFT SILICAS, ranging from $6 to $35 per ton, the latter price being for a high-quality air-floated grade in car lots. Carefully sized and graded grains for lithographic use fetch higher prices, good rock crystal sells for a minimum of around $2 per lb., fusing-quartz crystals may bring as much as 80¢ per lb. ($>1/4$-in. sizes).

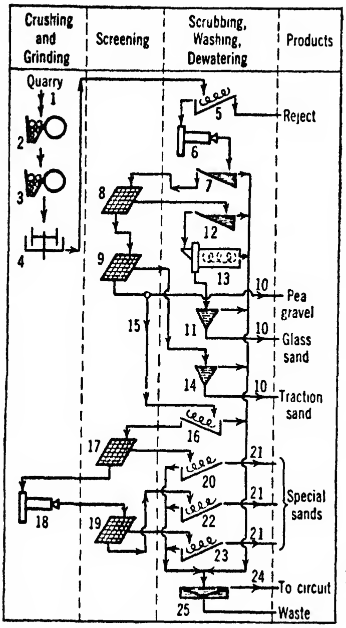
Glass sand, potter's flint, and the classes of ground quartz or sand used in ceramic industries are valued for their SiO_2 content and for freedom from iron, titanium, and other impurities that stain the product. Chemical purity is less important for some other uses, even where the product is to be melted, as in metallurgical quartz, but is even more important in the case of fusing quartz or sand for making fused silica ware, for which purpose physical structure also may be important, particularly if optical properties and an especially good appearance are desired. Purity, however, has to be considered in respect to quartz for lining acid towers or for making sodium silicate and silicon carbide; indirectly, too, it may affect refractoriness of ganister (for brick), molding sand (especially steel-molding sand); or again it may indicate substances that unfit sand for general industrial uses, although specification is merely for a reasonably clean, hard, tough material.

Piezoelectric crystals must not only be untwinned but also must be free from flaws, cracks, bubbles, inclusions, veils, or other defects. They should not be unduly clouded and preferably should possess at least two natural faces to permit the mass to be orientated crystallographically. Although size limits are not rigid, those weighing 1 to 10 lb. are preferred. American instrument makers pay $3 to $15 per lb. for rough crystals and recover only about 5% as finished plates.

Treatment varies according to character of crude and size and nature of product. Outlines of treatments for various products are given in Fig. 61. Flowsheets for special sand plants are shown in Figs. 62 to 63.

Decker's Creek Sand Co., Fig. 62 (*34 #2 PQ 45*).

Location: Greer, W. Va.
Capacity: 50 t.p.h.
Crude: High-silica loose sandstone.
Products: Glass sand, traction sand, blast sand, building sand, filter sand.
Water: From creek against 600 ft. vertical head by 4-stage centrifugal pump; consumption about 1,400 g.p.m.



Legend for Fig. 62:

1. 5 @ 4-ton dump trucks, about 1/2 mi.
2. 1 @ 28×36-in. Traylor jaw crusher.
3. 1 @ 12×20-in. jaw crusher.
4. 1 @ 9-ft. Lewiston wet pan.
5. 2 @ 30-in.×12-ft. Lewiston screw washers.
6. 1 @ 5×10-ft. Marcy rod mill with light rod load, used as a scrubber.
7. 2 @ 48-in.×20-ft. Akins simplex classifiers with 6-ft. boil sections (perforated plates (1/2-in. apertures) under sand side at about mid-length), 18-lb. water.
8. 2 sets of 2 @ 4×5-ft. Hum-mer screens in tandem, 20-m. Monel-wire cloth.
9. Trommel, 10-m. aperture.
10. Stockpile by flume.
11. 2 @ 6-ft. Allen cones.
12. 1 @ 54-in.×20-ft. Akins simplex classifier.
13. 1 @ 4×10-ft. Hardinge spiral classifier.
14. 1 @ 6-ft. Allen cone.
15. As needed for special sands on order.
16. 2 @ 20-in. Lewiston screw washers.
17. 2 @ 4×5-ft. Hum-mer screens.
18. 1 @ 4×8-ft. Hardinge rod mill.

24. 1 @ 1,200-g.p.m. centrifugal pump, 125-ft. vertical lift.
25. 1 @ 85-ft. traction thickener.

Fig. 62. Decker's Creek Sand Co.

Summary. Disintegration by jaw crusher; pan and rod mills, followed by washing and screening of washed sands to specification sizes; rewashing of sized special sands.

Central Silica Co., Fig. 63 (*44 #9 RP 41*).

Location: Glass Rock, Ohio.
Capacity: 1,600 tons per 24 hr.
Crude: 99.9% + SiO_2 grains (about 50-m.), cemented by loam and clay; about 0.05% Fe_2O_3.
Products: See items 15, 17, 21, and 22 of *Legend;* dust-collector dust (<400-m.) is sold for soaps and scouring powders.
Water consumption: 1,800 g.p.m.

Legend for Fig. 63:

1. 1 3/4-cyd. shovel; 7-ton trucks.
2. 1 @ 24×36-in. jaw crusher, 3-in. open setting.
3. 30-in. belt conveyor; 1 @ 500-ton and 1 @ 700-ton concrete-stave storage silos.
4. 2 Lewiston wet pans, 5/16-in. punched apertures in hardened-steel bottom plate, 30-in. tires, 15 r.p.m.; operated with about 4-in. layer.
5. 4 revolving screens, 10-m. aperture.
6. 2 @ 16-ft. spiral disk washers.
7. 2 as (6).
8. 2 as (6).
9. 2 as (6).
10. Deister shaking tables.
11. About 0.04% Fe_2O_3; drained to about 6% moisture; dried on steam driers (200-lb. p.s.i.); vibrating feeder.
12. Acid leach and wash.
13. Conveyor; drain bin; drier (140° F.).

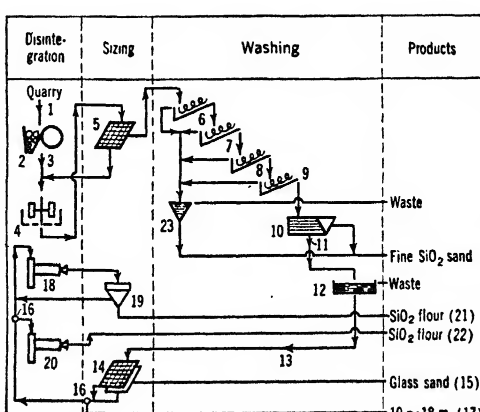

Fig. 63. Central Silica Co.

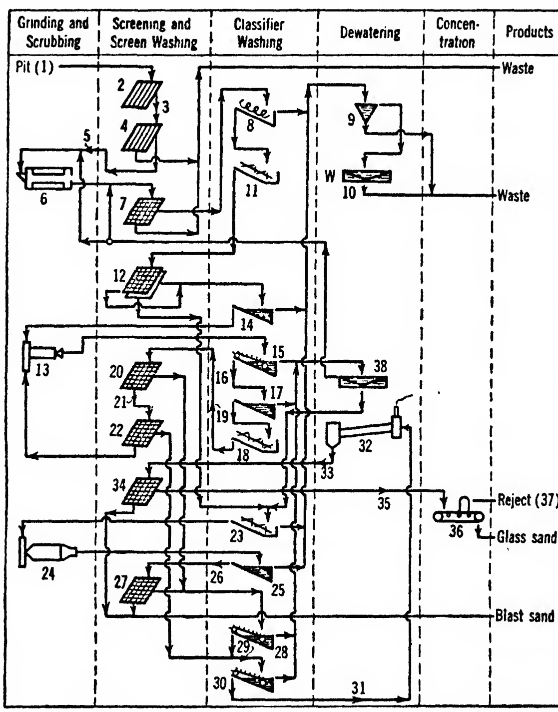
14. Deister-Multirap screens, 18- and 20-m. cloth.
15. 100% <20-m., 40% >50-m., 70% >70-m., 96% >100-m.; 0.01% Fe_2O_3.
16. Alternative.
17. Sand-blast sand, etc.
18. 1 @ 8×22-ft. pebble mill, flint-block lining.
19. 1 @ 12-ft. Sturtevant rubber-lined air classifier.
20. 1 @ 8-ft. Hardinge air-swept mill.
21. <200-m. for pottery.
22. <140-m. for foundry use.
23. Deslimer.

Summary. Friable sandstone disintegrated by wet-panning; washed repeatedly to remove clay and loam; tabled and acid-leached to remove Fe_2O_3; sized for glass sand; dry-ground with air classification for silica flours.

P. J. Weisel, Inc., Fig. 64 (*IC 6937*).

Location: Corona, Calif.
Capacity: 17.5 t.p.h.
Crude: Coarse sand embedded in clay. Sizing analysis: 1/2~1/4-in., 8%; 1/4-in.~200-m., 62%; <200-m. (clay and fine sand), 30%. Sand and small pebbles almost wholly SiO_2.
Products: Glass sand: 30~200-m.; SiO_2, 94.5 to 96%; Al_2O_3, 2.5 to 3.5%; K_2O, Na_2O, etc., 1.8 to 2.3%; Fe_2O_3, 0.03 to 0.04%. Blast sand, 6~14-m.
Cost is about $2 per ton of finished sand, including 35¢ for storage, trucking, and car-loading.



Legend for Fig. 64:

1. 3/4-cyd. power scraper.
2. Pit grizzly, 90-lb. rail, 20 ft. long, 12-in. spacing, +10° slope; material dragged up by pit scraper; oversize sledged through.
3. Loading hopper; 1 @ 24-in.×250-ft. belt conveyor, 33% slope, 190 f.p.m.
4. 1 @ 4×12-ft. squirrel-cage grizzly, made of old 1 1/2-in. pump rods welded to spider rings, 4-in. clear aperture.
5. 1 @ 10×10-ft. hopper; 1 @ 12-in.×6-ft. screw feeder.
6. 1 @ 4×5-ft. revolving scrubber; slope 1 1/2 i.p.f., with longitudinal lifters and a low retaining ring; about 150 g.p.m. of water added.
7. 1 @ 4×11-ft. trommel on same shaft as (6), 1/2-in. round holes; oversize a negligible quantity of clay lumps.
8. 1 @ 16-in.×10-ft. single-screw washer, 18° slope, 18 r.p.m.
9. 1 @ 7-ft. cone.
10. 1 @ 16-ft. spiral-rake thickener, 4 2/3 m.p.r.
11. 1 @ 26-in.×12-ft. log-type scrubber (see Sec. 10, Art. 4), 65 r.p.m.; no overflow.
12. 1 @ 3×6-ft. 2-deck mechanical vibrating screen, 30° slope, 6- and 14-m. apertures.
13. 1 @ 6×18-ft. tube mill, silex lined (about 5×15-ft. inside), charged with 23,000 lb. 3- and 4-in. Danish pebble; 60% solids.
14. 1 @ 2×16-ft. rake classifier, 32 s.p.m.
15. 1 @ 18-in.×16-ft. drag belt, 10° slope, 48 f.p.m.
16. 1 @ 6×6×12-in.×26-ft. belt-bucket elevator, 250 f.p.m.
17. 1 @ 3×16-ft. rake classifier.
18. 1 @ 8-ft. and 1 @ 10-ft. as (11) in parallel.
19. 1 @ 3-way revolving distributor.
20. 3 @ 3×6-ft. vibrating screens in parallel, 30-m. brass cloth.
21. 1 @ 6×6×9-in.×20-ft. belt-bucket elevator, 250 f.p.m., wood housing.
22. 2 @ 3×6-ft. Hum-mer screens, 30-m. cloth.
23. 1 as (11).
24. 1 @ 8-ft. double-cone grinding mill, silex lined, run without tumbling charge.
25. 1 as (17).
26. 1 @ 6×6×9-in.×36-ft. belt-bucket elevator, 250 f.p.m.

FIG. 64. P. J. WEISEL, INC.

Legend for Fig. 64—Continued:

27. 1 @ 3×6-ft. unbalanced-pulley type vibrating screen, 600 v.p.m., 30-m. cloth.
28. 1 @ 18-in.×14-ft. drag belt.
29. 1 as (21).
30. 1 @ 24-in.×14-ft. drag belt.
31. Drainage bin; scraper; 9-in.×9-ft. screw conveyor; 1 as (21); 1 @ 12-in.×30-ft. belt conveyor.
32. 1 @ 6×20-ft. direct-indirect rotary drier; dries 6 t.p.h. from 8 or 10% moisture to dryness with consumption of 33 cu. ft. per min. of natural gas.
33. 1 @ 5×5×5-in.×30-ft. chain-bucket elevator, sheet-steel housing.
34. 1 @ 3×6-ft. Hum-mer screen, 16-m. aperture, for skimming trash.
35. Air box in which sand is dropped in a sheet across a current of air for cooling and de-dusting. Dust is about 15% >80-m., 40% >100-m., mostly mica.
36. Induction-type magnetic separator.
37. 70% >60-m., mostly mica, garnet, dark silicates, and metallic ores.
38. 1 @ 10-ft. spiral-rake thickener, 3 1/2 r.p.m.

Summary. Natural sand scrubbed, washed, and sized at 1/2-in. and oversize rejected; undersize rescrubbed, washed, and a 6~14-m. blast sand cut out; remainder is classified, ground through 30-m. in closed circuit, is deslimed, joined with the natural washed <30-m. material, dried, de-dusted, and run over a magnetic separator for finished glass sand.

At Whitehead Bros. Co., Dividing Creek, N. J., foundry-sand plant (*46 #2 RP 52*) crude sand is scalped at 14-m.; undersize is deslimed in a hydro-bowl classifier and then classified into 8 sizes in a Fahrenwald sizer; classifier sands are dewatered in rake classifiers; all overflows are thickened and the thickened product classified in a rake classifier; all products are dried in an oil-fired rotary drier.

35. REFRACTORIES

Properties. Furnace linings and other refractory products are designed primarily to withstand high temperatures. No material showing obvious fusion after being heated slowly to 2,750° F. can be called a refractory. Other desirable attributes are resistance to slagging (chemical action), abrasion (physical wear), and spalling (thermal shock). The ideal refractory also should have the strength to resist either the pressure from a heavy load of molten metal in a furnace or the complex stresses in roof structures, and also be a poor conductor of heat and electricity. No one substance possesses all these virtues; hence a variety of materials are commercially employed. According to chemical composition they are of three classes, *viz.*, acid, neutral, and basic. Another division is between (1) hewn or cut blocks, (2) brick and other molded shapes, (3) mortars, and (4) crushed or granular materials applied

Table 17. Properties of refractory raw materials

Material	Approximate formula	Melting point, °F.		Density	Hardness (Mohs)	Commercial sources
		Pure	Commercial			
Alumina:						
Bauxite	$Al_2O_3 \cdot 2H_2O$	3,722	3,272 to 3,668	2.0 to 2.6	1 to 3	Imported; Ark.

a Apparent; true density and hardness much higher.

as loose aggregates to be rammed into place with or without binder. Quartzite (MICA SCHIST), diatomite, olivine, and soapstone are almost the only substances marketed as refractory blocks shaped from natural stone, and these are relatively minor items in the industry as a whole. About 60% of all refractory brick are fire-clay brick, 30% are silica (GANISTER) brick, and of the remaining 10%, over half are chrome and/or magnesite brick. Minor materials include carbon, kyanite, fused mullite, zircon, spinel, carborundum, olivine, bone ash, and oxides of aluminum, titanium, zirconium, beryllium, thorium, yttrium, etc. Metals also might be included; protected by cooling water, they are widely used for boilers, jackets, tuyères, cooling plates of blast furnaces and steam power plants. Important properties of various raw refractory materials are given in Table 17. Properties of refractory brick are given in Table 18.

Table 18. Refractory brick *a*

	Kind	Raw material	Melting point		Firing temperature

12	Nitrides, etc.	....	" 42	" 2,000	?	?

a At 400 to 500° C. CO reduces Fe_2O_3 and deposits C in the interior of the brick with harmful effect. Alternately reducing and oxidizing atmosphere has a harmful effect on chrome ore products over 1,000° C. SiC is destroyed by oxidizing atmospheres over 1,300° C. Gaseous alkalies reduce refractoriness.

Uses. The iron and steel industry probably uses 50% of the total sales of refractories, public utilities 20%, nonferrous smelting 6%, cement and lime plants 5%, glass plants 5%, oil refineries 4%, ceramic and miscellaneous 10%.

Production. Germany, Belgium, Great Britain, France, Italy, and other industrial countries are large producers of refractories, although the United States probably produces most. About one-third of the clay firebrick, almost three-fourths of the silica brick, and much of the chrome and magnesite shapes are manufactured in Pennsylvania, Missouri, Ohio, and Kentucky. They normally rank in the order named. The industry is represented in at least 33 states, but these four account for roughly 80% of the domestic total. Production quantities are given in Table 19.

e Data not available.
f Average 1925, 1927, and 1929.

Selling. Refractory-product sales are more sensitive even than the metallurgical industries to an oncoming recession and do not pick up again until well along in the ensuing recovery. Nevertheless, prices of standard refractory materials are altered only infrequently. Until 1929 the trend was gradually upward, owing in part to depletion of certain easily accessible deposits of fire clay and other materials, and in part to improvements in quality and more exacting service requirements. Price quotations for brick are for standard 9-in. brick; other sizes and shapes are subject to extras ranging from a small advance for wedges or keys to a substantial differential on soaps and splits, and still higher extras on little-used special shapes. First-quality firebrick, after being quoted f.o.b. plant (Central Pennsylvania, Ohio, or Kentucky) at \$43 to \$46 per M for several years dropped to \$35 in 1932, recovered to \$45, and in 1937 rose to \$54. Since a thousand firebricks weigh around 3 1/2 tons, prices at eastern steel works run \$7 to \$10 higher owing to freight. Second-quality firebricks are nominally \$5 cheaper than first-quality, and silica bricks tend to cost the same as first-quality fire-clay brick in the East, higher in the West. Kyanite bricks range from 45¢ to \$1 each and zirconium bricks have sold at \$1.10 each. Fused Al_2O_3, SiC, and MgO bricks all sell around \$1 each; extra high (80%) Al_2O_3 bricks, over 25¢ (\$260 per M).

Treatment. Firebrick is usually made from a mixture of refractory raw clay, burned flint clay, and raw refractory plastic clay. The flint clay usually makes up the bulk of the

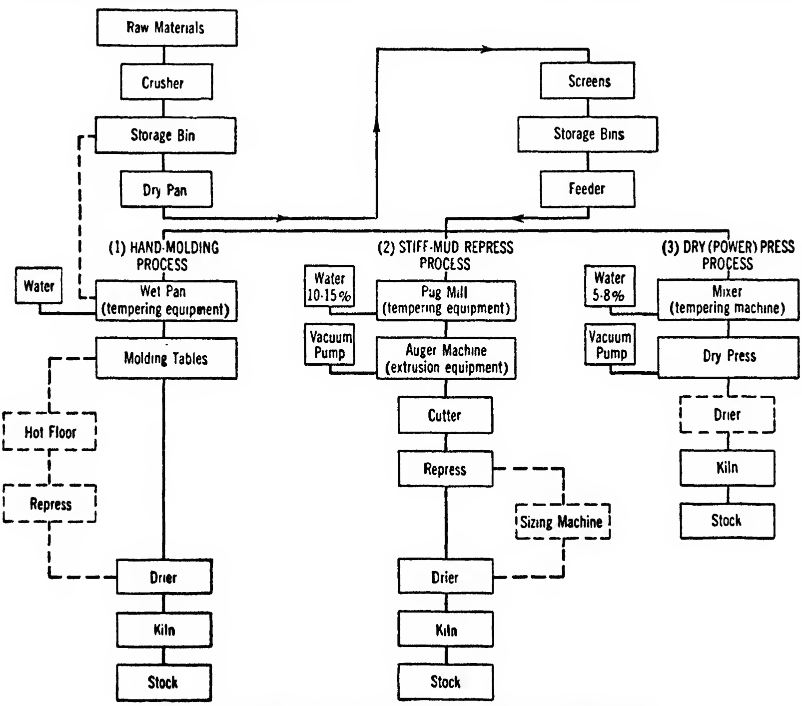

FIG. 65. Methods of manufacturing fire-clay brick (*IMR 624*).

mixture, and since it shrinks on firing, usually has to be precalcined. Mixed sizes are better; fine material alone is unsatisfactory for brick making. The term GROG means any calcined, broken, or ground products (including old firebrick, glass pots, and other manufacturing waste) used to reduce firing shrinkage. Fig. 65 shows three methods of manufacture: Hand molding, stiff-mud repressing, and dry pressing. Dry-pressed bricks are somewhat cheaper to manufacture than stiff-mud; being formed under pressures of 1,000 to 4,000 lb. per sq. in., they have virtually no drying shrinkage. Fire-clay bricks made by stiff-mud repress method are typically harder, tougher, and denser than dry-pressed bricks. Bricks made by any of the three processes are fired in tunnel or periodic kilns, the former being more economical for large, steady production. Maximum temperatures range from 2,300° to 2,500° F. according to materials and properties desired.

Silica bricks are made from crushed quartzite mixed with 2% CaO and H_2O. Owing to sudden expansion changes during firing, they must be handled carefully. They are burned in periodic kilns

at about 2,700° to 2,750° F. The dry process can make larger shapes than machine molding, but the bulk of the output is hand molded.

Magnesite brick is made from grain (DEAD-BURNED) magnesite (Art. 25), and chrome brick from crushed raw or calcined chrome ore (Sec. 2, Art. 11). They are burned at high (say, 2,700° F.) temperatures. In periodic kilns, half the space is lost because individual magnesite brick has to be surrounded by already-burned silica brick so each will have to support only its own weight. Both chrome and magnesite brick and other shapes are made in increasing quantities without firing. Owing to careful grain sizing and high forming pressures, unburned bricks are denser, heavier, and shrink less in service, though not quite so strong. Unburned chrome brick may contain 20% dead-burned magnesite. At least one domestic manufacturer melts synthetic $Al_2O_3 \cdot SiO_2$ mixtures in electric furnace and casts the product in suitable molds.

36. SALINES (GENERAL)

Description and uses. In addition to common salt, potash, borates, and nitrates, other soluble salts are recovered directly from natural brines, playas, marsh, or bedded deposits. Most important of these are sodium sulphate (used in Kraft paper, stock medicines, glass, dyeing, etc.); trona and other sodium carbonates (one of the most useful industrial chemicals); and epsom salts and other magnesium compounds (used in various industries as well as in medicine).

Occurrence. Natural salts constitute only a small percentage of the total production of sodium sulphates and carbonates, the latter especially being made chiefly in chemical plants using NaCl, but the treatment of brines and saltworks bitterns has become the principal source of magnesium salts, calcium chloride, and bromine; and iodine is produced to a considerable extent from oil-well brines. Imported sodium sulphate is made from waste $MgSO_4$ from the German (Stassfurt) potash industry. Brine wells are important sources of salines. In several Western States, sodium carbonates and/or sulphates occur naturally in considerable quantities in marshes and dried ponds, but the chief sources are the brines of alkali lakes, especially Owens Lake and Searles Lake; reefs of trona; and more or less bedded deposits (often overlain with clay). The largest mineral deposit in the world is the ocean, which contains a variety of useful elements.

Production. In 1937 record quantities of natural sodium compounds were recovered in the United States: 104,711 tons of carbonates valued at $1,191,485, and 80,053 tons of salt cake and Glauber's salt worth $599,266. The total quantity of natural magnesium salts (chiefly $MgSO_4$ and $MgCl_2$, but including some hydroxide and oxide and excluding large quantities of $MgCl_2$ used in manufacture of metallic Mg) produced from brine wells and sea water and sold or used in 1937 aggregated 64,777 tons valued at $1,578,527; domestic output of bromine was 13,100 tons valued at $5,180,177; of iodine, 299,286 lb. valued at $242,422 (imports, 1,967,148 lb.); and the calcium-magnesium chloride from natural brines amounted to 101,547 short tons worth $1,295,403. Foreign countries producing miscellaneous salines include Chile, Germany, U.S.S.R., Japan, Italy, Palestine, and in fact most salt-producing countries.

Selling. Since arid regions are rarely populous, markets for most salines are remote from the deposits and often can be supplied more advantageously by chemical works or imports; freight charges ordinarily limit the market radius. The average price of natural sodium carbonates fell from $20.30 per short ton in 1926 to below $11 in 1936, f.o.b. domestic plants in the West, compared with typical New York quotations of around $25. For sodium sulphate the price has been steadier, averaging around $7 for the natural western product compared with $13 to $15 in New York. High-grade magnesium carbonate (technical), made from eastern dolomite, is typically around 6¢ per lb. but the California sea-water products range in price from $40 to $100 per ton, f.o.b. plant, and an increasing proportion is converted into dead-burned magnesite selling for $25; $MgCl_2 \cdot 4H_2O$ is worth on the average about $10 per ton and $MgSO_4 \cdot 7H_2O$ around $28 per ton f.o.b. plant (1938). Calcium chloride averages well under $20 per ton, although flake chloride in late years has usually cost consumers at least $23 delivered; liquid $CaCl_2$ (40 to 45%) is quoted (1935–38) around $7.50 f.o.b. works. The Br content of ethylene tetrabromide has been valued by producers during the 1930's around 20¢ per lb., although quoted nominally at 30¢ or more. Crude iodine, pegged by Chilean producers for many years at $3.89 per lb., New York, was reduced by 1937 to around 90¢, owing to American competition.

Treatment. Recovery of Mg compounds, Br, I, $CaCl_2$, etc., from bitterns, sea water, or artificial brines involves complicated chemical procedures, in addition to evaporation and crystallization. Solid-salt crudes are treated by usual ore-dressing procedures, employing a saturated solution of the salts for circuit liquor. Mud is readily removed in log washers; tabling and froth flotation are accomplished satisfactorily in such solutions without further solution of soluble minerals. Sodium sulphate has been freed from mud purely mechanically and shipped in its natural state. In other places it has been leached in place or in vats, the warm, saturated solution being cooled later to precipitate Glauber's salt ($Na_2SO_4 \cdot 10H_2O$).

At Casper, Wyo., two ponds are used, brine being pumped from one pond to the other in order to recover each new crop of crystals. At Great Salt Lake, crude Glauber's-salt shales, lying under sand or precipitated by winter temperatures, is scooped by dragline into cars and hauled to plant. Refining consists in crushing, dissolving the salt, eliminating sand by classifiers, settling the solution, and evaporating to deposit either crystals or anhydrous salt cake (*139 #6 J 55*). At Wabuska, Nev., however, natural temperatures were high enough in the dry season to yield thenardite (anhydrous Na_2SO_4) instead of $Na_2SO_4 \cdot 10H_2O$ on solar evaporation.

37. SALT

Properties. Common salt (halite, NaCl) is a brittle mineral with conchoidal FRACTURE. HARDNESS is 2.5; SP. GR., 2.1 to 2.6; pure crystal generally weighs 136 lb. per cu. ft. Cubical crystals are common, less common are fibrous and stalactitic forms. Impurities, notably iron, frequently impart yellow or brown shades but the peculiar reddish tinge in solar crystals is thought to be organic in origin. Though readily soluble in water, NaCl is scarcely more soluble in boiling than in ice-cold water.

Uses. Salt is said to have over 1,500 uses. In the United States more than one-half the total consumption is used in making heavy chemicals, of which soda alkalies are most important. It is the direct source of chlorine and its derivatives, and of soda ash, caustic soda, sodium sulphate; and is the indirect source of many other sodium compounds. Roughly 15% of the domestic consumption is used in sugar and food-product industries. Other large consuming industries are leather, glue, dyes, textiles, soap, vegetable oils and greases, and glass and ceramics. As a refrigerant, salt is used in freezing and packing ice cream as well as in the brines at mechanical refrigerating plants. In several industries its main use is as a regenerator in zeolite water softening. Other quantities are used as weed-killer, ice remover, and for stabilizing and dust-laying on secondary roads. The average American uses only about 6 lb. of salt a year as condiment and another 6 lb. may be needed for preserving and processing foods, but the average per capita consumption is almost 70 lb. per year. Relatively insignificant quantities are used in metallurgy as flux and for chloridizing metals.

Occurrence. Salt is the commonest highly soluble mineral known and is the principal saline in sea water, which contains on the average 2.7% NaCl and 0.8% of other salts, chiefly sulphates of Ca, Mg, and K and small amounts of $CaCO_3$, $MgCl_2$, and $MgBr_2$. Great Salt Lake, Utah, and the Dead Sea, Palestine, are examples of inland salt lakes; in the form of natural or connate brine salt is widely distributed in sedimentary rocks and stored in glacial gravels or soils. Often these underground brines are bitterns containing other dissolved salts in proportions greatly different than in ordinary sea water, though most of them originally were fed by the sea. Rock salt occurs in beds and also in salt structures variously known as bosses, plugs, ridges, or domes, which are found in areas of sedimentary rocks throughout the world, but are structurally and genetically different from ordinary bedded deposits. Rock-salt beds or lenses are interstratified with sediments of all geologic ages (sandstones, shales, and, less commonly, limestones), also with gypsum, anhydrite, potash, and other salts. Single beds may be hundreds of feet thick and extend over many miles. The Permian Basin, which runs from Kansas into Texas and covers about 100,000 sq. miles, is virtually all underlain by salt. Some deposits contain almost pure salt but other saline minerals are abundant in many deposits and clay and sand are always likely to be admixed more or less intimately, at least in some portions of a deposit. As commercial sources of salt, bedded deposits are by far the most important.

Production. The United States is the leading producer of salt, furnishing about 30% of the world production of about 25,740,000 metric tons in 1929. Germany and Great Britain each produce about 2,000,000 tons annually and the total for Europe substantially exceeds the domestic output. Moreover about one-half of the domestic output never takes the form of dry salt but is pumped from the earth as brine and used directly for the manufacture of chemicals, chiefly by electrolysis, which yields soda and chlorine or joint products. The salt industry is not quite so nearly depression-proof as the food industries, but sales of domestic salt during the depression year 1932 were only about 25% less than in the boom year 1929 (whereas the general industrial index was off 46%); by 1936 they had topped the 1929 peak, rising to a new record of 9,241,564 short tons valued at $24,131,733 in 1937. Of this quantity 4,631,580 was salt in brine, 2,030,432 tons was rock salt, and 2,579,552 was manufactured or evaporated salt.

Selling. Refined table salt ordinarily costs 2 to 5¢ per lb. retail but this grade can be bought wholesale at the mine in bulk and sized, at less than $10 per ton, the spread being due almost as much to the cost of packaging as to transportation or distributing expenses. The yearly average value of all domestic salt sales f.o.b. mines in 1937 was $2.61 per short ton compared with 5-yr. averages of $3.32 in 1925–29 and $3.01 in 1930–34. This average is reduced by the inclusion of brine salt for chemical manufacture, which is valued at only about 40¢ per ton of salt contained. However, the average for rock salt is only a trifle over $3 per ton and for manufactured (evaporated) salt a little over $6.

Treatment methods vary widely according to the character of crude and the use toward which preparation is directed. ROCK SALT as mined is sold and shipped for many pur-

poses after a minimum of hand picking and sizing. At RETSOF (*129 A 381*) 8∼6-in. lump; and $^3/_8$∼$^1/_4$-in., $^1/_4$∼$^5/_{32}$-in., $^5/_{32}$-in.∼8-m., and <8-m. sizes are shipped after preparation by screening on shaking and vibrating screens following graded crushing in Sturtevant vertical rotary crushers and rolls, taking small reductions in each crusher and rejecting the largest oversize, which is mostly shale. For certain purposes, however, small amounts of impurity are objectionable. Thus for human consumption, absence of Ca, which causes deliquescence, and of Mg, which makes the salt bitter, are requisite, and refining is required, involving solution and recrystallization.

When WELL MINING (see Weigel, *129 A 405*) is practiced, whether for rock salt or for recovery of connate brines from porous strata, the crude arrives at the surface as a saturated solution, and is thereafter evaporated with more or less care, and the crystal crop is more or less refined subsequently, according to the market; or, as in lime-soda plants, the raw brine enters directly into the consumer's process. When natural unsaturated brines (salt-lake or ocean) constitute the crudes, evaporation to a saturated brine or to the point of actual crystallization is a preliminary to refining. For detailed methods see Phelan, *Bul 146 USBM*. All crystallization methods depend upon the fact that sodium chloride is less soluble in water at high temperatures than the majority of the accompanying salts. Hence if the solution is clarified of sand, clay, and the relatively insoluble salts, such as gypsum, while near saturation with sodium chloride at the prevailing elevated temperature, further evaporation at elevated temperature yields a crop of NaCl crystal that is reasonably pure. Cooling is no particular aid in the crystallization of the salt (see Fig. 58) and is a hindrance to separation because of reduced solubility of the other salts present. The precipitated salt is drained, washed with its own brine (*i.e.*, by the addition of small amounts of fresh water), centrifuged, dried, crushed, and sized according to market demands. Soap flotation may be used after crystallization, instead of filtration or sedimentation, to remove clay and gypsum, if high purity is not demanded. Evaporation may be atmospheric in certain climates, but the crop is of lower purity than when crystallization is effected at higher temperatures.

38. SAND AND GRAVEL

Properties and uses. Sand and gravel are best described as unconsolidated granular material >200-m. resulting from natural disintegration of rocks. Sand is <$^1/_4$- or $^1/_{10}$-in. and the top limit for gravel is about 3 $^1/_2$-in. Both weigh normally 90 to 110 lb. per cu. ft. Artificial or STONE-SAND is finely crushed stone, carefully screened. Shale, soft sandstone, coal, and other friable, unsound particles render material unfit for concrete aggregate; organic impurities and clay also are deleterious. Market sizes are mostly combinations of the following typical plant products: (1) Gravel, 2 $^1/_2$∼1 $^1/_2$-in.; (2) gravel, 1 $^1/_2$∼$^3/_4$-in.; (3) fine gravel, $^3/_4$∼$^3/_8$-in.; (4) roofing gravel, $^5/_8$∼$^1/_4$-in. (or finer); (5) general purpose sand, or washed concrete sand, <$^1/_4$-in. (usually with a fineness modulus of 2.50 to 3.40); (6) asphalt sand, <10-m.; and (7) asphalt filler, <100-m. Nos. 1 to 5, and even No. 6, are used in concrete and for road surfacing, the finest used for correcting coarser sands. No. 5 is used also for mortar and for certain plasters.

More than one-half the sand and gravel produced is consumed in concrete construction, either highways or buildings. About two-thirds of all gravel is used for paving (including concrete, bituminous, and cheaper construction); the balance is used chiefly in buildings and for railroad ballast. More sand is used in building than in paving, but these uses together account for over three-fourths of the consumption, the balance being special sands (*q.v.*) and a small amount of railroad ballast and miscellaneous-purpose sand.

Occurrence. Sand and gravel are abundant in every state and country. Glacial deposits are chief sources in north central and northeastern United States, in Canada, and in the northern half of Europe. In coastal regions, marine deposits are the major source. Lake and dune sands are locally important. The most widely distributed deposits are stream-laid. Residual gravels are likely to be variable in hardness, whereas transported gravels are composed largely of dense, resistant particles, approaching quartz in hardness, and hence more desirable for most purposes. Fluvial deposits frequently show rough size gradation, but the beds vary in thickness and coarse sand or gravel may be interspersed with lenses of fine sand and clay. They usually overlie an eroded rock floor, but may be spread over fine sediments. Delta deposits occur at the mouths of rivers and as alluvial fans or cones where swift mountain streams debouch on wide plains. Old streams, in wide valleys, leave terrace deposits that may be workable. Marine and lake deposits are the best sorted, glacial deposits the poorest, often containing everything from big boulders to fine silt. Wind-blown sand is usually fine-grained. Even-grained sand, free of silt, is usually purest. Only careful prospecting will disclose the area, thickness, and shape of a given deposit; even more important is careful sampling to ascertain the natural size gradation and physical characteristics.

Production of sand and gravel in the United States reached a peak of 225,000,000 tons valued at $130,000,000 in 1929; in 1937 it was 189,660,423 tons worth $97,472,997. Production from noncommercial plants, including those owned by Federal and local government agencies, comprised 7% of total in 1929, 34% in 1937. The proportion of gravel was 55% of the total tonnage in 1929 and 67% in 1937. Imports and exports are quite small. World production figures are not available but probably run slightly more than twice the domestic figures, large quantities of sand and gravel being produced in Germany, Great Britain, the U.S.S.R., and other industrial countries for local consumption.

Selling. In 1932 the railroads got 81¢ per ton of sand and gravel carried, whereas average value f.o.b. plant was only 53¢. This illustrates the importance of local markets. Declining consumption in cities and towns and increased demand for interurban highways have fostered the growth of small portable plants that can be set up near the job.

Recommended size specifications for typical uses have been published by the Division of Simplified Practice, National Bureau of Standards, Washington, D. C. Allowable percentages of organic impurities, of clay or silt, and of soft, friable, or unsound particles vary with local conditions, information on which often can be obtained from the National Sand & Gravel Assoc., Washington, D. C.

In 1937, Bureau of Mines reports showed average value of railroad ballast sand as 24¢ per short ton, building sand 57¢, and paving sand 55¢; commercial gravel averaged 73¢ for building and 60¢ for paving.

Treatment method is determined primarily by the market. The prevailing factors are: (*a*) specifications, (*b*) yearly tonnage, (*c*) maximum daily tonnage, (*d*) character of consumption, *i.e.*, one-job, or the scattered, continuous demand of a settled community. The secondary determinants of method have to do with the deposit: its extent, uniformity, size distribution, and mineralogical character.

The principles of treatment are simple. Assuming satisfactory soundness of the stone, specifications deal primarily with size; in some cases additionally, there is minor emphasis on shape. Hence sizing is the key operation. It is performed on screens down to a lower size in the general range of 1/4-in. to 10-m., and by classification at finer sizes. If the deposit is deficient in fine sizes, it is usually cheaper to produce these by crushing than by excavating a larger tonnage and spoiling the excess oversize. Hence one or more stages of crushing is common practice, depending upon the maximum size of gravel. If fine sizes are in excess they must be spoiled. Consumption of the entire product of treatment is substantially never in step with production; some size or sizes are always in excess. Hence segregated storage is an essential operation in all plants, with provision for handling products in and out of storage. In connection with such handling, it is usual to arrange for proportional withdrawal from storage in order to satisfy specifications for blends comprising two or more short-range products.

Screens are almost invariably of vibrating or high-speed shaking types except when, as in small operations, installation of a sectional revolving screen over a compartmented bin saves enough in first cost of screen and associated transport machinery to justify the lower capacity and efficiency; or when considerable clay is present, and the more vigorous disintegrating action of the wash-trommel type is necessary. In some large plants separate screens are used for scalping and final grading (as at HIWASSEE DAM, Fig. 74), on the principle that total screen surface necessary at a given size split may be reduced (with corresponding reduction in operating cost) by taking circulating loads off the grading screens. Such an arrangement also allows greater flexibility in routing in the crushing plant.

Classifiers are usually of the sand-tank type (Sec. 8, Art. 8) in small plants, and of mechanical types (Sec. 8, Arts. 2 to 7) in large. The drag classifier is an effective deslimer, but is not so effective in making splits at a specified sand size as a classifier of the rake or spiral type. The sand tanks are substantially limited to desliming unless used with hydraulic water. Hydraulic classifiers (Sec. 8, Arts. 10 and 11) are used only for special sands; their capacities are too low for aggregate-sand plants.

Crushers are ordinarily of the hard-rock types, *i.e.*, jaw or gyratory for the primary, and reduction gyratory or cone crusher for the secondary. If crushing for aggregate sand is necessary, short-head cones, rolls, or rod mills are usual; occasionally an impact mill is used, even with hard gravel, for making an equiaxed product.

Storage is of the open, ground type in all but the smallest intermittent plants that run only for immediate shipment. The usual arrangement is a conveyor-fed stockpile over a tunnel conveyor, with sufficient live capacity for ordinary requirements, and traveling bucket cranes or bulldozers for moving dead material as necessary. Stockpiles of finished grades are often set over the same reclaiming conveyor, and constant-weight feeders used to permit blending during withdrawal. Equalizing storage is usually provided between pit and preparation plant, and frequently between the primary and secondary crushing plants to render the three operations mutually independent. The time of such independence ranges from a fraction of a day to several weeks.

Transport of material in process and into and out of storage is usually by belt conveyor except for fluid sand pulps, and in the unusual case where a high vertical : horizontal ratio is a structural necessity. The arrangements are legion; see Sec. 18, manufacturers' catalogues, and the detailed descriptions of operating plants in the technical periodicals of the industry. Short transfers of coarse material are usually made, however, by pan or apron conveyor, particularly when loading involves considerable

fall, as from a primary crusher, or the transfer must be made on a steeper incline than is possible on a belt conveyor. Sand-size pulps with high water content and slimes are elevated by centrifugal sand pumps (Sec. 18, Art. 17).

Separating and blending. Formulas for the quantities of materials of given size characteristics to be subtracted from or added to a given feed in order to yield a product of desired characteristics are given at Sec. 19, Eqs. 169 to 174.

Example 1. **Washing.** Given the sand, Table 20, Col. 1, what percentage must be taken away to satisfy the specification in Col. 2, and what will be the screen test of the resulting sand? SOLUTION: By inspection, if <200-m. only is taken away, the effect on screen test will be to approach the specification directly in so far as <200-m. is concerned, and this deduction will be subtractive as to all of the other figures of the sizing analysis, the change from the original analysis being less, the larger the number in the original analysis. If it is not attempted to remove all of the <200-m., a bowl-rake classifier can be operated to overflow only <200-m. and still leave not more than the specification limit of 6.5% <200-m. in the sand. Allowing for inefficiency of the apparatus, calculate for 5.0% <200-m. Then in Eq. 171, Sec. 19, $f_{200} = 19.5$, $c_{200} = 5$, $d_{200} = 100$, and $s = 0.15$, or 15% of the

Table 20. Screen analyses for Example 1

Mesh	Percentages passing						
	1	2	3	4	5	6	7
	Feed, f_n	Specification	Washed sand, c_n	Overflow, d_n	Washed sand, c_n	Overflow, d_n	Washed sand, c_n
4	96.0	95 to 100	95.2	....	95.2	....	95.0
8	87.3	70 to 90	85.0	....	84.5	....	84.2
14	70.5	50 to 70	65.3	....	63.8	....	63.1
28	51.0	30 to 50	42.3	....	40.2	....	38.8
48	37.1	15 to 30	26.0	....	23.3	100	21.4
100	27.0	8 to 13	14.1	100	11.0	96	8.8
200	19.5	0 to 6.5	5.0	95	3.0	71	1.0

feed must be overflowed. Now apply Eq. 173 successively to the various sizes to get the screen test of washed sand shown in Col. 3. This satisfies specification as to all except <100-m. To reduce this figure, the feed must be washed harder, in which case some >200-m. material will be overflowed. Assume that an overflow of the sizing shown in Col. 4 will be obtained in washing to 3.0% <200-m. Then $f_{200} = 19.5$, $c_{200} = 3.0$, and $d_{200} = 95$, whence $s = 0.18$, and the screen test of washed sand is as Col. 5. If the specification is changed to 5 to 10% <100-m. and 0 to 2% <200-m., remaining otherwise the same, the sand must, of course, be washed yet more deeply and overflow must have the characteristics given in Col. 6. Setting $c_{200} = 1.0$, d_{200} is 71.0, $s = 0.26$ and $c_{100} = 3.5$, which is too coarse for specification. If c_{100} is set at 5.0, $s = 0.24$ and $c_{200} = 3.0$, which is too fine. In other words, the specification sand cannot be made from the feed with a bowl-rake classifier overflowing material of normal size distribution. If, however, the material is treated in a hydro-bowl with hydraulic water, an overflow approximating Col. 4 can be made, with which, setting $c_{200} = 1.0$, $s = 0.20$ and the sand has the size distribution shown in Col. 7.

Example 2. **Screening.** When separation is effected by screening, the oversize always contains some undersize, so that s is greater than is to be calculated from the screen test of the feed on the basis of a clean split. The amount and distribution of undersize in oversize may be approximated from study of the tables of screen performances in Sec. 7. Once s is thus established the screen tests of the products may be approximated from Eq. 173, Sec. 19, which may be rewritten, for convenience, as $v_n(f_n - su_n)/(1 - s)$ or $u_n = [f_n - v_n(1 - s)]/s$, where v is oversize and u undersize, if some assumption is made as to distribution of undersize in oversize. If feed is moist (not wet) this undersize will be distributed principally between the coarsest and finest through-screen sizes, say one-quarter fines and three-quarters distributed 50% on the first test screen below the separating mesh, 38% on the second, and 12% on the third. In Table 21, Col. 1 was a screen test of feed to a relatively flat vibrating screen with 1 1/4-in. aperture. The feed was moist. Oversize should carry about 15% undersize. Hence, per 100 tons feed, oversize should be 26.5/0.85 = 31.2 tons ($s = 1 - 0.31 = 0.69$), and the 4.7 tons per 100 tons of undersize in this oversize should be 0.25 (4.7) = 1.2 tons <8-m., 0.5 (4.7 − 1.2) = 1.8 tons on 1-in., 1.3 tons on 3/4-in., and 0.4 tons on 1/2-in. Screen test of oversize on these assumptions is given in Col. 2 and calculated screen test of undersize from the formula in Col. 3.

Example 3. **Blending.** Prediction of the screen tests of a blend, knowing the screen tests of the ingredients and their proportions, is simple (Eq. 174, Sec. 19). The usual problem is to determine the proportions in which two stocks must be blended to meet a given specification. Table 22, Cols. 1 and 2, gives screen tests of two sands, and in Col. 3 is the specification to be met in blending them. If this specification can be met in entirety by simple blending, the smallest proportion of added sand (Col. 1) that will do it is that which gives the largest value of i when Eq. 172, Sec. 19, is applied. In the present case this is 0.67 for i_{100} (Col. 4), whence if 67 parts of a_n is added to 100 parts of f_n the screen test of b_n will be as in Col. 5.

Power: Push-button control from a central observation panel; warning to attendant posts by loudspeaker.

Labor: 19-man crew for excavation, transport, and washing.

Water: 2,500 g.p.m. from a nearby creek; static pressure on 8-in. line is 300 ft.; Worthington centrifugal pump, 250-h.p. motor.

Mill site: Sloping, 115-ft. fall in 386 ft.

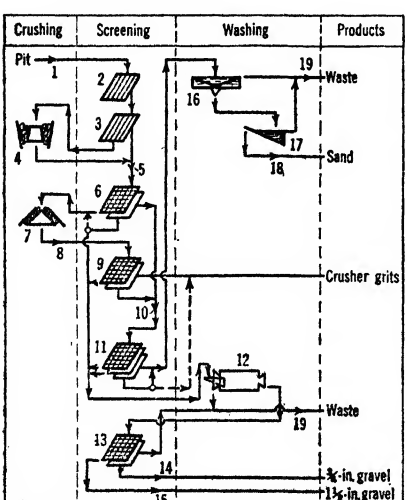

Fig. 66. Rosoff Sand & Gravel Corp.

Legend for Fig. 66:

1. 8-cyd. dump trucks; feed hopper with 3×6-ft. reciprocating-plate feeder.

2. Flat sledging grizzly on feed hopper, 100-lb. rail, 15-in. spacing; all sledged through.

3. 1 @ 54-in. 10-ring rotary grizzly, 4-in. spacing, 2 1/4-in. alloy-steel rings, 12 r.p.m.

4. 1 @ No. 16-B Telsmith gyratory crusher, 4-in. open setting.

5. Surge bin with 3×6-ft. reciprocating-plate feeder; 36-in. inclined conveyor.

6. 1 @ 5×12-ft. 2-deck Telsmith vibrating screen (Sec. 7, Art. 8), 1 1/2- and 3/4-in. openings; flap gate on 3/4-in. oversize regulated to send enough 1 1/2~3/4-in. material to (7) to produce substantially equal quantities of 1 1/2-in. and 3/4-in. gravel (see specifications) in plant products. Water added to undersize.

7. 1 @ 36-in. Telsmith Gyrasphere crusher (Sec. 4, Art. 7), 4 1/2-in. receiving opening; adjusted to produce desired proportions of <1 1/2-in. and <3/4-in.

8. 1 @ 18-in. conveyor.

9. 1 @ 3×10-ft. 2-deck vibrating screen, 3/4- and 1/4-in. cover, water sprays at 15- to 40-lb. pressure.

10. Hopper beneath screen (6).

Legend for Fig. 66—Continued:

11. 2 @ 5×12-ft. triple-deck Telsmith vibrating screens, 3/4-in., 1/4-in., and 8-m. screens; flap gate on lowest deck to divert part of 1/4~8-m. to <8-m.; water sprays at 15- to 40-lb. pressure.

12. 2 @ 6×10 1/2-ft. countercurrent scrubbers; water jets at 15- to 40-lb. pressure.

13. 2 @ 3×8-ft. 2-deck Telsmith vibrating screens, 3/4-in. and 1/4-in. screens.

14. 1 @ 24-in. conveyor; 1 @ 500-cyd. Blaw-Knox steel storage bin.

15. As (14).

16. 1 @ 24×6 1/2-ft. hydro-bowl classifier; 180 tons solid per hr., approx. 200-m. separation; underflow 50 to 60% solids.

17. 1 @ 9×25 1/2-ft. rake classifier, 2 1/4-in. per ft.; approx. 100-m. separation; sand about 20% moisture.

18. 24-in. belt conveyor; 500-cyd. Blaw-Knox steel storage bin.

19. 5 settling ponds, aggregate area about 10 acres.

Summary. Crudely split gravel >4-in. and >1 1/2-in. crushed in parallel stages in standard and high-speed gyratories to <5% >1 1/2-in.

Boston Sand & Gravel Co., Fig. 67 (*44 #1 RP 50*).

Location: Quonset Point, R. I. (special plant for naval base).
Crude: Glacial gravel with large boulders and some decomposed granite; gravel content about 60%.
Capacity: 200 t.p.h. feed.
Recovery: About 50%.
Water: 800 g.p.m. pumped from nearby stream.
Power: Purchased; comes 0.7 mi. from town at 550 volts.
Building: Plant unenclosed; has operated down to 16° F.
Hauling: 10-ton Sterling trucks.

Legend for Fig. 67:

1. Diesel shovel, 1 1/4-cyd.

2. End-dump trucks; short haul.

3. Rail grizzly, 12×20-in. openings, over a loading hopper; 2 1/2×5 1/2-ft. Telsmith plate feeder.

4. Not economical to install a primary crusher at this point.

5. 30-in.×153-ft. belt conveyor with full-length skirt boards.

6. Rotary grizzly, 4-in. spacing.

7. 1 @ 18×30-in. jaw crusher, 1 1/8-in. closed set; 60-hp. motor.

8. 1 @ 5×10-ft. Telsmith Pulsator screen, 2 1/2-in. aperture.

9. 1 @ No. 36 Gyrasphere crusher, 1 1/8-in. closed set; 75-hp. motor.

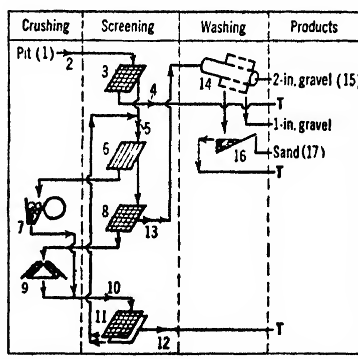
10. 1 @ 24-in.×96-ft. belt conveyor.

11. 1 @ 3×8-ft. 2-deck Pulsator screen, 1-in. (guard) and 3/8-in. apertures.

12. Contains much of the decomposed granite; discharged here to improve soundness tests.

13. 1 @ 24-in.×135-ft. belt conveyor.

14. 1 @ 5×18-ft. rotary washing screen, 10-ft. scrubber section (blank plate) and 12-ft. jacket, 1-in. and 3/8-in. apertures.



15. Blended with some of 1-in. product in chute to bin to make 2-in. Navy specification.

16. 1 @ 36-in. and 1 @ 48-in. classifier.

17. ± 1% <100-m.

FIG. 67. BOSTON SAND & GRAVEL CO.

Summary. Initial split at 2 1/2-in. on screens; oversize crushed to about 2-in. nominal limiting size in parallel streams of >4-in. and 4~2 1/2-in. materials, with rejection of <3/8-in. from crushed undersize before closing circuit on the 2 1/2-in. screen. Original gravel <2 1/2-in. and 2 1/2~3/8-in. crushed product washed and graded to 2-in. and 1-in. gravel and 3/8~100-m. sand.

Table 23. Sand sizings at Montgomery Gravel Co.

Screen, mesh	Per cent. passing	
	Specification	Product
4	95 to 100	98.5
8	....	85.5
16	35 to 75	69.0
30	....	49.3
50	10 to 20	15.9
100	1.5 to 7	2.8

Montgomery Gravel Co., Fig. 68 (*41 #8 RP 30*).

Location: Montgomery, Ala.
Capacity: 106 t.p.h. each of sands and gravel.
Crude: About 40% gravel.
Products: See Table 23.

Summary. Specification sand made by classifying out excess 16~50-m. and <150-m. Lack of storage compensated by mining an excess and wasting variable amounts of wanted sizes.

Legend for Fig. 68:

1. 12-in. Amsco Type H pump, 4,500 g.p.m. water and solids at a consistency ranging from 0 to 18% solids; receiving box.

2. Fixed screen, 30° slope, 3/16-in. sq. aperture. Undersize contains about 80% of total water and practically all <16-m.

3. 1 @ 36-in. flume with adjustable horizontal splitter; slope, 3 i.p.f.

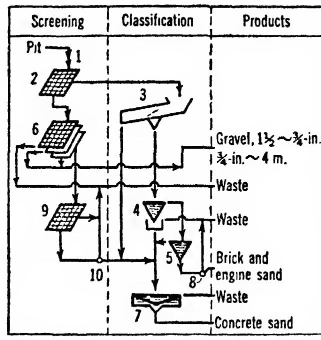
4. 1 @ 6-ft. Auto-vortex classifier (Sec. 8, Fig. 24); set for 16-m. split; surge box (1/2-cyd. capac.) with adjustable bottom gate under spigot; overflow wasted to maintain uniform feed rate to (7). Spigot product contains less than 2% <50-m. and a trace of <100-m.

5. 1 @ 8-ft. Auto-vortex classifier; set for 50-m. split; spigot, 1% >6-m., 2% <50-m.

6. 2 @ 3×8-ft. 3-deck Niagara screens, 1 1/2-, 3/4-, and 1/4-in. apertures.

7. 2 @ 15-ft. hydro-bowl classifiers, 1 1/2 m.p.r.; <150-m. overflow; spigot product, see Table 23.

8. Alternative.



9. 1 @ 24-in.×6-ft. Hendrick launder screen; slope, 2 in. per ft.; 10-m.×1/2-in. slotted apertures.

10. Splitter.

FIG. 68. MONTGOMERY GRAVEL CO.

Metropolitan Sand & Gravel Corp., Fig. 69 (*46 #2 RP 32*).

Location: Port Washington, N. Y.

Capacity: 800 cyd. per hr.

Crude: Bank gravel, 500 acres extent; mostly <2-in. with 85% sand, but only about 6% <80-m.

Legend for Fig. 69:

1. 1 @ 7-cyd. electric dragline, 110-ft. boom, 90-ft. face carried; 1 @ 160-cyd. steel hopper over loading tracks, top (30 ft. above track level) on level with dragline bench, can be moved ±40 ft. to a new loading position in about 20 min. by jacking up and taking weight on sand cars (2).

2. 4 @ 40-cyd. standard-gage gondola cars; Diesel locomotive; 1 mi. to crude storage.

3. 12,000-cyd. (live) storage under 300-ft. steel trestle through which hopper-bottom cars (2) dump; dump doors electrically operated by push-button control. Dump time about 2 min. Reclaiming tunnel 30 ft. below track level.

4. Jeffrey-Traylor vibrating feeder, and 1 @ 36-in.×140-ft. inclined belt conveyor drawing from end 50 ft. of stockpile; other 250 ft. drawn by vibrating feeders onto 1 @ 36-in. transfer belt; both at 500 f.p.m. Ball-bearing idlers; 5- and 6-ply belt throughout plant.

5. 1 @ 5×10-ft. 2-deck Ty-rock screen, 2-in. and 1 1/2-in. sq. openings.

6. Normal operation, when no call for 2~1 1/4-in.

7. 1 @ 36-in. Traylor reduction gyratory, 1 to 1 1/4-in. set.

8. 1 @ 24-in. belt conveyor to (4).

9. Alternative.

10. 1 @ 36-in.×322-ft. inclined (+4 i.p.f.) belt conveyor, 500 f.p.m.

11. Butterfly gate in conveyor-discharge chute.

12. 2 @ 5×23-ft. revolving scrubbers, 8-ft. blank section with retaining ring and about 250 steel balls; 3/8×3/4-in. and 1/10×3/4-in. wire screens; 18 r.p.m. Normal percentage scrubbed is

15 to 20, largely to increase fines for asphalt sand.

13. 2 @ 5×14-ft. Ripflo (vibrating) screens, 1/8×4-in. Ty-rod cover (0.063-in. wire), 40° slope.

14. Hopper; 1 @ 36-in.×140-ft. stacking conveyor.

15. Stockpile, 180,000-ton (60,000 tons live), 110 ft. high (max.), for dry-screened brick or plaster sand.

16. 2 @ 5×10-ft. 3-deck Ty-rock vibrating screens, 1 1/4-, 3/4-, and 1/8-in. apertures; run wet.

17. 1 @ 40 (diam.)×45-ft., 1,200-ton reinforced concrete bin (6 of these form the support for the plant structure).

18. 1 as (17).

19. 2 @ 12-ft. bowl-rake classifiers.

20. 1 @ 36×120-ft. stacker conveyor.

21. 1 @ 16,500-ton (live) stockpile; wet plaster or brick sand.

22. From one only.

23. 1 as (19).

24. 1 as (19).

25. 1 @ 24-in. belt conveyor.

26. 1 @ 8,000-ton (live) stockpile; asphalt sand.

27. 1 @ 7 (deep)×12×24-ft. settling tank.

28. Slimy water.

29. Pump.

30. Items *a*, *b*, *c*, *d* are 4 Greenville automatic cones.

31. 1 as (25).

32. 1 @ 4×12-ft. 2-deck Ty-rock vibrating screen, 1/2- and 1/4-in. apertures.

33. 1 as (17); 1/2~1/4-in.

34. 1 as (17); 3/4~1/2-in.

35. 1 as (25).

36. 1 as (32), 3/16-in. and 1/10-in. apertures.

37. 1 as (17); pea gravel, 1/4~3/16-in.

38. 1 as (17); grits, 3/16~1/10-in.

39. 1 @ 12-in.×65-ft. bucket elevator; distributing hopper.

40. 4 @ 22-in. Greenville impact crushers; 1,800 r.p.m.; 25-hp. motor; 15 t.p.h. Feed 96% >8-m.; product, 60% <8-m., 20% <50-m., 7.5% <100-m., 3% <200-m. Plates run 24 hr., are turned, and run 16 to 24 hr. additional.

41. Elevator.

42. 1 @ 2×7-ft. washing screen, 16-m. aperture.

43. As needed: Draw from hopper (14) to screw conveyor to 1 @ 5×24-ft. rotary oil-fired drier. Dust to storage bin, then blended into asphalt sand.

44. 1 as (17).

45. 1 @ 36-in.×160-ft. cross conveyor.

46. 1 @ 36-in.×350-ft. tunnel conveyor under all storage units as indicated.

47. Gravel only to (48).

48. 1 @ 4×14-ft. 2-deck Ty-rock rinsing screen, 3/4- and 1/8-in. Ty-rod cover.

49. 1 @ 36×650-ft. conveyor to loading dock, 500 f.p.m.; 1,500 t.p.h.; short conveyor with Merrick Weightometer.

50. 1 @ 30-in. belt conveyor; 1 @ 4-compartment circular concrete-block truck-loading bin.

51. 90 @ 500- to 750-cyd. barges to coast points.

Products: 2~1 1/4-in., 1 1/2~1 1/4-in., 1 1/4~3/4-in., 3/4~1/2-in., 1/2~1/4-in., 1/4~3/16-in., 3/16~1/10-in., <1/10-in. dry screened brick and plaster sand, <1/10-in. washed brick and plaster sand, <1/10-in. dried sand, <1/10-in. asphalt sand with up to 25% <80-m., <3/16-in. concrete sand blended to specification.

Water: Fresh, from an artificial lake.

Power: Total connected, 1,486 hp. All drives either V-belt or direct through gear reducers.

Building: Steel and concrete.

Summary. A fine-gravel deposit graded by screening to 1/8-in., and by water classification of finer sizes to produce 10 to 12 primary sizes, from which blended mixtures are made according to demand in drawing from storage.

Grand Coulee Dam, Fig. 70 (*129 A 156*).

Location: Coulee Dam, Wash.

Capacity: 1,000 t.p.h. nominal; 1,700 t.p.h. normal; 2,500 t.p.h. maximum throughput.

Specifications: Cobbles, 6~3-in.; coarse gravel, 3~1 1/2-in.; medium gravel, 1 1/2~3/4-in.; fine gravel, 3/4~1/4-in.; sand: FINENESS MODULUS (= Σ cumulative >4-, >8-, >14-, >28-, >48-, >100-m./100) 2.5 to 3.0; distribution, see Table 24.

Table 24. Quantities and sizes (*a*) of sands at Grand Coulee

37. Sand storage, 3,500 tons; see Table 24.
38. Remote-control gates in tunnel running under piles.
39. 48-in. conveyor to mixer storage.

Fig. 70. Grand Coulee Dam plant.

Summary. Pit gravel scalped at 16-in.; 16∼6-in. crushed through 6-in., sized on vibrating screens into 4 grades over the range 6- to 1/4-in. and thoroughly washed; sand <1/4-in. (4-m. max.) roughly deslimed in drag classifiers, and slime and the bulk of the drag sand wasted; the residue of drag sands graded into three sizes by bowl-rake classifiers and then blended to specification. Storage (open-ground) provided between pit and crusher, between crushing and screening, and for the separate gravels and sands prior to blending.

Shasta Dam, Fig. 71 (*33 #9 PQ 43*).

Location: Near Redding, Calif.
Crude: Gravel with excess of cobbles and dearth of fine sand; small percentage of soft stone.
Capacity: 1,500 t.p.h.
Water: 7,400 g.p.m. by 1 @ 5,000-g.p.m. and 1 @ 2,400-g.p.m. turbine-type pump from Sacramento River.

Legend for Fig. 71:

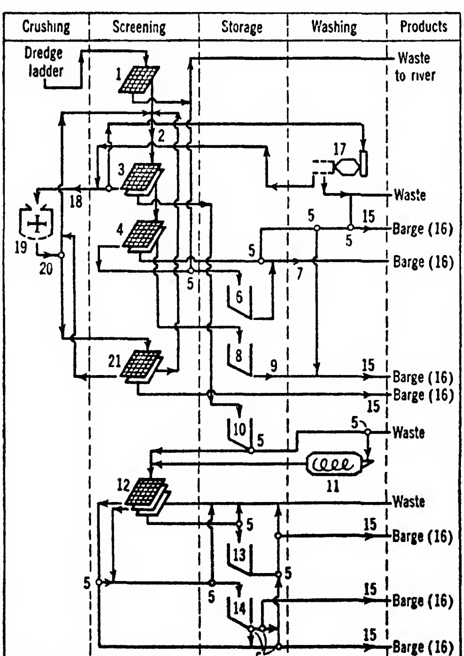
49. 1 @ 5 × 10-ft. 2-deck Ty-rock screen, 5/8- and 1/8-in. wire cloth.
50. 1 @ 18-in. × 78-ft. belt conveyor.
51. 1 as (47), set for <3/8-in. product.
52. 1 @ 18-in. × 90-ft. belt conveyor.
53. 1 @ 18-in. × 152-ft. belt conveyor.
54. Stockpile, 1,000 tons live capacity.
55. 1 @ 18-in. × 229-ft. belt conveyor; Merrick Weightometer.
56. 1 @ 8 × 12-ft. Marcy rod mill.
57. Alternative.
58. Rotary-vane feeder; Feed-o-weight.
59. 1 @ 30-in. × 772-ft. reclaiming conveyor.
60. Blended-sand stockpile with Bodinson traveling-wing tripper; 30,000-ton live capacity; 5 motor-operated gravity gates to tunnel.
61. 1 @ 36-in. × 445-ft. conveyor with Weightometer to conveying system to dam, 9.6 mi.
62. 8 Pan-American rougher jigs; hutch product to a base-metal trap; overflow to a cleaner jig; hutch to a Pan-American revolving amalgamator; tailing to a scavenger jig together with the trap settlings.

Summary. Primary crushing and rejection of unsound rock by washing primary <1/4-in.; scrubbing of all 6∼1/4-in. primary gravel, followed by wet screening to four gravel sizes. Three sand sizes made on washed primary <1/4-in. material by classification, unsound material being first further disintegrated by light ball milling. Deficit of sand made up by crushing current excess gravel sizes and grinding in wet rod mill. Some gold recovery by usual placer-jig methods (see Sec. 2, Art. 20).

Dravo Corp., Keystone Sand Division, Fig. 72 (*33 #11 PQ 83; 43 #4 RP 36*).
Location: Ohio River, near Pittsburgh, Pa.
Capacity: 250 t.p.h. of aggregate.



Legend for Fig. 72:

1. Low-head screen, 5-in. aperture. Solid section at feed end covered with 1-in. sheet rubber overlain by a frame of 3 × 1/2-in. steel skid bars on edge mounted to permit some vertical movement; these and the rubber take the shock of boulders (@ 20-in. max.).
2. Elevator similar to digging string but smaller and lighter; 41-ft. centers.
3. 1 @ 6 × 14-ft. 2-deck A-C vibrating screen. Perforated plate, 3/4- to 2 1/2-in. apertures on top deck, 3/8-in. on lower. Screen on lower end of upper deck changed according to conditions.
4. 2 @ 5 × 12-ft. 2-deck A-C vibrating screens, 1/4-in. and 1/8-in. perforated plate.
5. Alternative.
6. Surge bin.
7. 1 @ 24-in. × 45-ft. boom belt conveyor.
8. Steel sand tank.
9. Dewatering bucket elevator.
10. Surge bin.
11. 6 × 18-ft. Allswede 4-compartment revolving scrubber, loaded with 6 tons @ 4 1/2-in. forged-steel balls.
12. 5 × 12-ft. 3-deck Low-head screen, 3/4-in., 3/8-in., and 1/8- or 1/4-in. apertures.
13. 1 as (6).
14. 1 as (6).
15. 1 @ 24-in. × 20-ft. boom belt conveyor, or (7), according to position of barge. 1 No. 7 and 1 No. 15 loading conveyor each side of boat.
16. 500-ton.

FIG. 72. DRAVO CORP., Keystone Sand Division.

Legend for Fig. 72—Continued:

17. 1 @ 7-ft.×48-in. Hardinge conical scrubber with 48-in. dewatering section, $5/8 \times 1/4$-in. slots. Used only when there is much clay.

18. 1 @ 24-in.×60-ft. belt conveyor.

19. 1 Pennsylvania C-7-38 Impactor (Sec. 4, Art. 9), manganese-steel hammers and nickel-iron breaker plates, 100-hp. variable-speed (300- to 900-r.p.m.) motor; feed rate, 80 to 90 t.p.h.

20. 1 as (6).

21. 1 @ 5×12-ft. 2-deck Low-head screen, aperture varied according to demand for crushed gravel.

Crude: River gravel with more or less clay.
Products: Crushed and mixed gravels and sands.
Dredge: 4-cu. ft. buckets, 74-ft. ladder, 40-ft. digging depth; 30 buckets per min. = 350 to 400 t.p.h.

Summary. Fine gravels, natural, crushed or mixed, and specification sands made with little storage by use of a variable-speed hammer mill (giving control of fineness), together with changing screen covers, a highly flexible chute and surge-bin system, and some spoilage, permitting blending of running streams. This is an ingenious method of surmounting the lack of the usual storage space available to land plants.

39. SLATE

Properties. The distinguishing characteristic of slate is its ready cleavage along a series of nearly parallel, closely spaced smooth planes. The position of these cleavage planes was determined by the metamorphosing pressures, and is entirely independent of the original bedding of the rock. The chief minerals in slate are present in the following quantities: muscovite, 38 to 40%; chlorite, 6 to 18; quartz, 31 to 45; hematite, 3 to 6; rutile, 1 to 1.5%. Carbonates, graphite, biotite, feldspars, pyrite, and a variety of other minerals may also be present in minor quantities.

As a structural material, hardness, crushing strength, and density are considerations for slate as for other building stones. Special properties are its wide range of color and tint, permanence of color, cleavage and grain, possible shear zones or cross cleavage (which may cause the stone to form irregular worthless slivers), jointing, bedding (which may cause breakage or undesirable changes in color), and heat and electrical conductivity or resistivity.

Uses are indicated in Table 25. Roofing is the leading use. Structural and sanitary slate includes baseboards, stair treads and risers, mantels, sinks and dripboards, shower and toilet stalls, etc.; slate pencils are included under school slates, a declining item. Granules are used in banded briquettes as well as for surfacing flexible shingles and roll roofing. Pulverized slate or flour is used as filler in roofing, mastic, paint, linoleum, rubber, and molded electrical goods, and as a mild abrasive in soaps and polishes.

Table 25. Slate sold by producers in the United States, 1928 and 1937

Use	1928 (peak year)		1937			
	Equivalent short tons	Value	Sq. ft.	Equivalent short tons	Value	Average per ton
Roofing slate	177,310	$ 5,411,332	365,800	137,400	$2,728,109	$19.86

Flagstones, etc.	6,290	184,184	1,215,490	8,670	73,554	8.48
Total slate as dimension stone	232,380	$ 9,003,820	....	167,550	$4,027,308	$24.04
Granules and flour	413,980	2,468,471	....	277,010	1,578,014	5.70
Grand total sales	646,360	$11,472,291	....	444,560	$5,605,322	$12.61

Occurrence. Commercial slate is found only where the original strata were largely clayey and subsequent earth movement has been sufficient to induce recrystallization. Shales in the central Mississippi Valley, for example, have not been folded intensely enough to yield slate.

An ideal deposit should have little or no overburden and should yield a minimum of water. The strata should stand nearly vertical; if the slaty cleavage is nearly flat and parallel to the strike, quarrying is greatly simplified. In horizontal beds waste may be excessive and selective quarrying may be impossible; if the cleavage dips too steeply, quarry blocks may not easily be wedged loose from the floor.

Production. The United States, Great Britain, Belgium, and the U.S.S.R. have been the largest producers of commercial slate, roughly in the order named, but slate is quarried in many foreign countries. Domestic output is centered chiefly in eastern Pennsylvania (two districts) and nearby Maryland, the Vermont-New York district, Virginia, and Maine; production in other states is relatively small.

Selling. Freight rates largely fix the market range of slate products worth less than about $50 a ton (see Table 25). The price per square of roofing slates varies with the district and with the size, larger sizes being worth more; the national average in 1938 was $6.98 compared with $7.47 in 1937, and $11.20 in 1928.

Treatment. For roofing-slate manufacture the blocks are split with chisel and mallet until slabs $^3/_{16}$ or $^1/_4$ in. thick are obtained. These are trimmed to standard sizes with a heavy blade operated with a foot treadle or with a power-driven rotary trimmer that

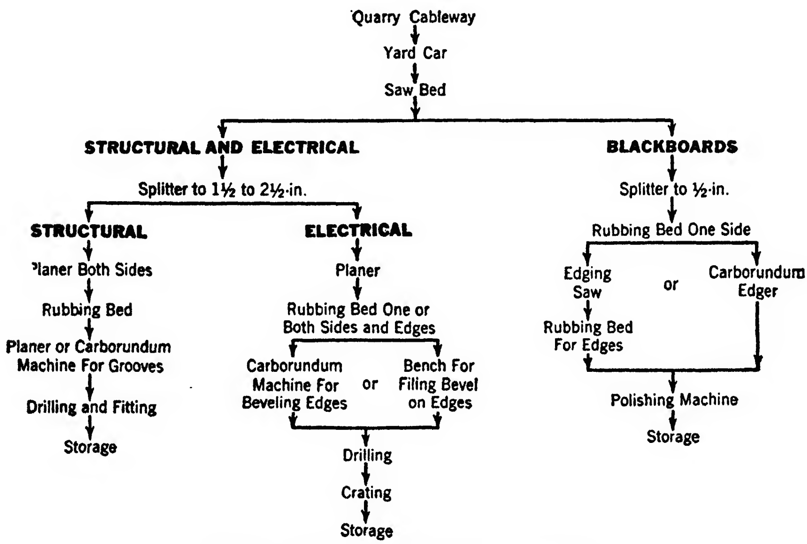

FIG. 73. Mill for structural and electrical slate.

embodies the shearing action of a lawn mower. Slate for the manufacture of blackboards, electrical panels, and structural products (Fig. 73) first is split to the approximate thickness desired and then smoothed and reduced to uniform size by planers, rubbing beds, and surfacing machines similar to those used in marble mills (Art. 40). Carborundum wheels generally are used for COPING (trimming edges of slabs and cutting them into strips).

The manufacture of granules for surfacing prepared roofing is partly a branch of the slate industry, but other materials, such as trap rock, rhyolite, silica, and burned clay are also used for granules. The object of the milling process is to prepare a clean product ranging from 8- to 35-m. in size and to make as small a proportion of fines as possible, since these are largely unmarketable. The final granules should be dust-free. Early mills comprised graded crushing in jaw crusher and rolls operated dry, with intermediate scalping of limiting-screen undersize, but modern plants treat the production problem as one of making stone sand, drying, and screening out the granule cut dry. In either case, the recovery of 10~35-m. material will rarely run above 50 to 60% of the crude, and use must normally be found for the finer materials, if the plant is to be in a competitive position in the field. Raw materials are carefully selected as to color, but granules are also colored artificially, and the synthetic colors are gaining in popularity.

40. STONE, DIMENSION

Properties. Stone used in construction of walls is of four main types, *viz.*, cut or finished stone, ashlar, rough building (or monumental) stone, and rubble. Only the first is accurately shaped to dimension. Ashlar, however, is sawed, planed, or otherwise trimmed to rectangular blocks. Paving

blocks, curbing, and flagging are also classed as dimension stone, but RIPRAP (large, irregular blocks used for shore protection and the like) is classed ordinarily with crushed and broken stone.

Principal varieties of dimension stone are granite, sandstone, limestone, and marble. Slate (Art. 39) and limestone (Art. 24) are usually classed separately. Relatively few rock occurrences can be utilized as dimension-stone quarries. No deposit that has closely spaced cracks, lines of weakness, or joints can be so used, because only sound blocks of moderate to large size can be marketed. Uniform texture and grain size, constant and attractive color, and freedom from impurities that may cause stains or deterioration further affect the utility of a deposit. Hardness has little influence on use except as it affects workability. Even strength is usually disregarded, since any sound structural stone is many times stronger than necessary for any ordinary service. The base course of the 550-ft. Washington Monument, for example, carries a load of only 700 lb. per sq. in., and most structural stones will sustain a crushing load of 10,000 to 25,000 lb. per sq. in. Porosity ranges from 1 to 10% for commercial sandstones, 0.5 to 5% for limestones; other rocks usually under 0.1%. Weights per cu. ft. range from 140 to 180 lb. Great variation is shown in the endurance of stones. Tests of enduring qualities are now made in laboratories by repeated freezing and thawing, and no reliable quarryman will ship exterior stone that fails to pass the most rigid of such tests. However, conditions of outcrops that have been exposed for countless years may afford even better evidence as to resistance to weathering. Igneous rocks as a class suffer most from temperature changes, calcareous sandstones and limestone from acid atmospheres.

Occurrence. Granite deposits usually are fairly uniform over considerable areas and are deep. Sedimentary rocks naturally vary in attitude and may be less persistent, requiring more careful exploration. Marble, soapstone, verde antique, and other metamorphic rocks are even more irregular in extent and quality.

Production. Principal granite-block-producing states in order of value of production in 1938 were Vermont, Massachusetts, Georgia, Maine, and Minnesota. Roughly half the quantity and two-thirds of the value of all building limestone is produced in Indiana. Ohio is by far the leading source of sandstone, New York and Pennsylvania being the only other important producing states. Tennessee leads in marble, but by no wide margin over Georgia and Vermont. See Table 26.

Table 26. Dimension stone sold or used by producers in the United States (by kind) (*MY*)

	1929		1932		1937

Many foreign building and ornamental stones are used in this country as well as abroad. Notable examples are Italian, French, Belgian, English, and African marbles; Italian travertine; Mexican onyx; and the granite of Scotland, Finland, Norway, and Sweden.

Selling. The average prices of cut, sawed, and finished building stone in the United States as reported by producers tended to decline after 1929. In 1938 the average per cu. ft. for finished building marble was $5.47, for granite $3.39, and for sandstone, $1.48. Prices of monumental marble have fluctuated from $3 to $5; for 1938 the figure was $4.77. Monumental granite averaged $2.70 per cu. ft. in 1938, compared with $3.75 in 1929; for dressed stone only, the average in 1938 was $6.96, compared with 90¢ per cu. ft. for rough stone.

Inasmuch as the stone from no two quarries is exactly alike, specifications relate chiefly to workmanship and surface finish. The choice of color, texture, or general appearance is made by architects and builders to suit the design of the building. The American Association of State Highway Officials, however, has issued specifications for ashlar and rubble to be used in bridges and incidental structures —chiefly in relation to soundness, durability, and freedom from seams, cracks, or other defects. Patterned floors require tile of different colors that blend well and that do not differ too greatly in resistance to abrasion. Stone for sanitary uses should have a low ratio of absorption; this is also desirable for marble floorings, to resist staining. Stone for laboratory use should resist chemical action.

Dimension stone is often sold in rough blocks directly to dealers or manufacturers. Some quarry men, however, have mills where they saw blocks and so can sell either slabs or rough blocks to dealers or manufacturers. Most of the largest structural-stone companies have their own finishing mills and so can take contracts for whole structures and fabricate according to specifications. Monumental granite is mostly sold in rough blocks to manufacturers of memorials, although a few important quarry units turn out finished monuments. Monumental marble is usually manufactured by producing companies and sold to the retail monument trade. Paving stones and curbing are sold direct to contractors or municipalities, or through dealers.

Treatment. In limestone, sandstone, and marble mills, quarry blocks are sliced by GANG SAWS, which are soft-iron blades set in a reciprocating frame and fed with sand or steel abrasive. Subsequent cuts are made chiefly with diamond- or carborundum-toothed circular saws. Further smoothing of slabs may be done on planers similar to those used in machine shops. Still smoother surfaces are obtained on a RUBBING BED, a flat rotating cast-iron table 12 to 16 ft. in diameter. The block or slab of stone is held by a stop or barrier and bottom surface is ground smooth by sand and water fed onto the top of the table. Carborundum machines are widely used for cutting cornices, moldings, bevels, etc.; carving is done by pneumatic tools or sandblasting (rarely by hand).

Granite, being so much harder, used to be split to approximate dimensions by drilling and wedging and then smoothed roughly by surfacing machines consisting of powerful pneumatic hammers that chipped the surface, much as a rock-drill bit cuts into a drill hole. In modern mills, however, even granite is cut by gang saws or circular saws with steel shot as abrasive. Rubbing beds are not used for granite, but the principle is the same except that the buffing machine has a power-driven rotary head which is guided over the surface of the stationary stone, wearing it down with successively finer grades of steel shot, carborundum grit, or emery. Final polishing is done with a buffer-head charged with PUTTY POWDER (fine-grained SnO_2). Carborundum machines are used for irregular cuts, but must be guided carefully and kept supplied with plenty of water. Sand-blast carving is particularly adapted to granite. The stone is covered with a rubberlike dope which is cut away with a scalpel to form the design before the sand blast is turned on.

41. STONE (CRUSHED)

Properties and uses. About two-thirds of the crushed and broken stone produced in the United States is limestone; basalt or trap rock (diorite and other dark igneous rocks) is a poor second. Granite, sandstone, and miscellaneous stones of various kinds are all employed. Apart from its mineralogical character, crushed stone may be classified according to its physical and chemical properties, cleanliness, and gradation (see Table 27). For uses of crushed limestone see Art. 24. Other kinds of crushed stone are used almost entirely for riprap, concrete, and road metal or railroad ballast. Slate and other granules are used for roofing and similar decorative purposes (Art. 39). Miscellaneous uses of crushed stone include terrazzo, sewage, filter beds, asphalt and other fillers, and stone sand. Trap rock has a high reputation for road construction and finds its main outlet in that field. Granite is

a See p. 107.

not used so much for highways as for concrete, railroad ballast, and riprap. Sandstone is employed to some extent for road base, but more for other uses.

Production in the United States, exclusive of that used for making cement and lime, was 123,072,820 short tons in 1938 (Table 28), compared with 131,262,010 in 1937, and an all-time peak of around 145,000,000 tons in 1929. Including stone used for making cement and lime, the 1938 total was 155,950,000 tons. Production of aggregates only (concrete stone, road metal, and railroad ballast), however, reached a peak in 1938 of 94,763,050 tons valued at $88,767,221 due to an increase in noncommercial operations (by Federal and local government bodies) to 34,508,880 tons purchased at $35,785,401. See also Sec. 1, Fig. 1.

Occurrence. Igneous rocks are most abundant in rugged territory, and the largest areas are those least used, being traversed by few highways or railroads and remote from large population centers. Chief developments are in outcrops, often isolated and comparatively limited in extent, near large cities. Granites and other coarse-grained igneous rocks are utilized extensively in New England and southward following the Appalachian Mountains, and in Wisconsin and California. Trap rocks, finer grained, are used extensively in Connecticut, Massachusetts, New Jersey, New York, Pennsylvania, Washington, and California. Light-colored igneous rocks (trachyte, andesite, rhyolite, and tuff) are found principally in Rocky Mountain and Western States, about half the miscellaneous stone being reported from California. Igneous deposits by nature are more uniform in quality, usually stand out on higher ground, and are covered with less overburden. However, the rock near the surface may be inferior owing to weathering. Limestones in general are associated with low valleys and heavier overburden. They are less uniform, more distorted by folds. Favorable localities for local deposits can often be predicted from State and Federal geological reports, so that a study of transportation facilities can be made before actual prospecting in the field.

Selling. Average prices f.o.b. plant as reported by Bureau of Mines usually range from around 75¢ per ton for railroad ballast to about $1 for carefully sized concrete and road material. Riprap may sell for less than 50¢. Asphalt filler and powdered limestone may bring upward of $2 per ton. Markets must be nearby, seldom more than 50 to 100 miles away. Transportation charges are often more than the price at bin. Since stone is widely distributed, small roadside quarries may be opened temporarily, if a job is too far from existing plants. Acceptance is usually at the point of delivery, hence rejection losses for unsuitable stone may include delivery, unloading, and handling, as well as plant costs. Demand is highly seasonal; very little stone moves in winter except in Southern and Pacific States. In early spring, highway demand is relatively greater first for smaller sizes for patching winter damage, and later for the surface-chipping and oiling programs before heavy tourist travel begins. Larger sizes for concrete and new road surfacing are in greater demand later in the season after grading is completed and before freezing weather arrives.

Definite progress has been made in the elimination of unnecessary variations in specifications. Federal and State Government specifications are usually standard for a given locality, but are changed

from time to time. Heavy irregular fragments are used for riprap; dense and less soluble igneous rocks are best suited for this service, but since the main requirement is low price, large quantities of limestone are so used. Owing to local variations in available rock deposits, character of traffic, and climatic conditions, no standard specifications can be given for concrete aggregate and road metal. The most important qualities for highway use are wear and toughness. The FRENCH COEFFICIENT

is an arbitrary way of expressing WEAR; it is equivalent to 40 divided by the percentage wear resulting from rotating a 5-kg. sample in a closed cylinder for a specified period. In the RATTLER TEST, large cast-iron spheres are used to accelerate the wear. TOUGHNESS is resistance to impact, ordinarily measured by the PAGE TEST on a cylindrical core of the sample. STRENGTH is resistance to fracture under steady pressure. SOUNDNESS is considered in relation to weathering. The SODIUM SULPHATE TEST simulates freezing and thawing action by causing crystallization of the salt within pores of the rock. Closely sized samples are soaked in saturated solution at constant temperature for 18 hr., dried at 105° C. to 110° C., and then cooled to room temperature. After repeating the soaking and drying a specified number of times (usually 5), specimens are washed free of salt, dried, and screened again. The amount passing the same sieves on which the sample was retained before test gives desired

information. Additional information on portions of sample $^3/_4$-in. or larger is noted as to number of pieces showing disintegration, splitting, crumbling, cracking, or flaking. Magnesium sulphate may be used in like manner but gives widely different results; in fact, no soundness test other than actual service is considered conclusive.

Size specifications as listed by Goldbeck (*Oct. 1931 Crushed Stone Jour. 5*) are shown in Table 29.

Treatment. Owing to frequent changes in specifications, flexibility of operations, permitting production of a variety of sizes and mixtures, and provision for segregated storage are desirable. Hand loading is still practiced in quarries where selection of stone is necessary, also in small plants.

Crushing. Blake-type crushers and gyratories are usually used for primary breaking of hard rocks, single-roll jaw crushers for the softer limestones and other nonabrasive rocks. Corrugated jaw plates on jaw crushers are normally used to compensate for the supposed tendency of the machine to produce slabby pieces, equiaxed fragments being most desired because they tend to increase the workability of concrete. Secondary crushing is usually in reduction gyratories or standard cones. Fine crushing is practiced increasingly, cones or rolls being used for hard rock and hammer mills for material not too abrasive. Stone sand and dust (mostly limestone) may be made in hammer mills, but ball, rod, tube, ball-bearing, and roller (edge-runner) mills are also used, especially on harder rocks. Wet-grinding is used only for coarser sands and then only if the finest material is to be discarded.

Screening. Trommels are still the usual choice for screening in small plants, because they are low in first cost and serve as distributors over the bins, simplifying design. In large modern plants revolving screens are used principally for scalping of larger sizes preliminary to crushing or following revolving scrubbers. Vibrating screens are preferred for openings of 1-in. or smaller and are used for much larger rock (see Sec. 7, Art. 9). Bar grizzlies are used for scalping where accurate sizing is not required; some plants use live-roll grizzlies.

Washing has become increasingly important. Fishtail sprays over screens suffice for removing small amounts of dust, but to break up tough clay, log washers or blade mills are used. Intermediate are various types of revolving scrubber sections on revolving screens. Recent conical and cylindrical scrubbers operate like ball mills, grinding clay balls with the stone itself.

Storage. Large ground-storage areas are commonly needed since storage bins for more than one day's run are expensive. The major portion of output is shipped as produced, consequently stock piling is practiced not so much to meet future demands as to balance variations in demand for different sizes. Careful dumping in layers or other suitable precautions are necessary to avoid segregation.

Portable plants have been devised to meet need for wayside quarries for jobs too far from commercial plants. They consist normally of a small crusher, an elevator, a sectional revolving screen, and one or two stacker conveyors. In addition to saving trucking costs on long hauls, these light plants can be shifted from point to point of the deposit, facilitating selective quarrying (see Sec. 4, Art. 12).

Shape of particles to be used in concrete aggregates is an important part of the specification in many large contracts. FLATS and SLIVERS, usually defined as particles with a maximum dimension 5 or more times the minimum dimension, are usually limited to 5 or 10% of the total. But the method of determination of such content is not standardized, with the result that a given product rejected on a 10% tolerance by one inspector may pass a 5% tolerance with another inspector. In part this is due to the substantial impossibility of sampling a coarse aggregate to obtain a sample small enough in bulk to permit economical testing even by machine screening (see Sec. 19, Art. 1).

Testing. Progress toward a standard test (which assumes a proper sample) trends toward rescreening of oversize made on a square-mesh sieve on rectangular-mesh sieves with apertures ranging up to 10 or more times the width, with some provision for aiding passage by hand in the case of the coarser sizes. Actually such tests are substantially meaningless in the coarse sizes, and it is probable that even in fine sizes skilled visual inspection or, better, counting of an actual sand or a photograph thereof gives a more accurate picture of shape distribution.

Effect of flats and slivers in coarse aggregates is by no means clearly established. The usual assertion is that such pieces assume positions with long axes horizontal in pouring concrete and consequently produce voids underneath them; that they tend to concentrate in the surface and, being there, fail and cause surface failure, etc. But the supporting evidence is not strong, and there is much *contra.* If the whole aggregate were flat, *e.g.*, if made with slate or schist or some slabby gravels, there is no doubt that a pour would contain many voids, but such an aggregate is very different from anything producible from a reasonably homogeneous rock by any crushing method.

The case against slivery sand is well established in that sand-cement mixtures with equiaxed grains are definitely more fluid than those with a high percentage of slivers, and consequently can be more heavily loaded with sand for a given penetrability into the pores of the coarse aggregate in pouring a concrete mix. The resulting saving in cement justifies insistence on equiaxed sand.

Production of equiaxed grains from a given rock depends in part on the crusher used and in part on the method of operation. Large reduction ratios tend to produce a more slabby coarse aggregate than small reductions. This follows from the fact that large reduction ratios go with large nip angles in most crushers, and that the first breakage in such cases consists in slabbing off corners into pieces that usually are not nipped again,

and consequently do not suffer the cross breaks necessary to reduce them to equiaxed particles. With small reduction ratios the break surfaces radiate from the points of application of the load toward the interior of the particle, with many forks making relatively large angles with the initial surfaces and with each other, which tends toward an equiaxed product. Any machine, therefore, so built or so operated as to load the particle to be broken in such a way that the lines of action of the loads run toward the center of the particle will tend to produce equiaxed breaking, and *vice versa*. Large throw tends to have much the same effect as large reduction ratio. Choke feeding, which aids nip angle, reduces flats, as does also the use of high circulating loads.

In grinding for equiaxed grains the machine should be of such type and so operated as to accentuate abrasive action, at least toward the end of the grinding operation. This tends to round off corners and thin edges, and while it means that the slime loss may be fairly high, it thereby reduces the amount of nonequiaxed sand. It is effected by crowding the grinding zone to the extent that steel-to-steel contacts are minimized.

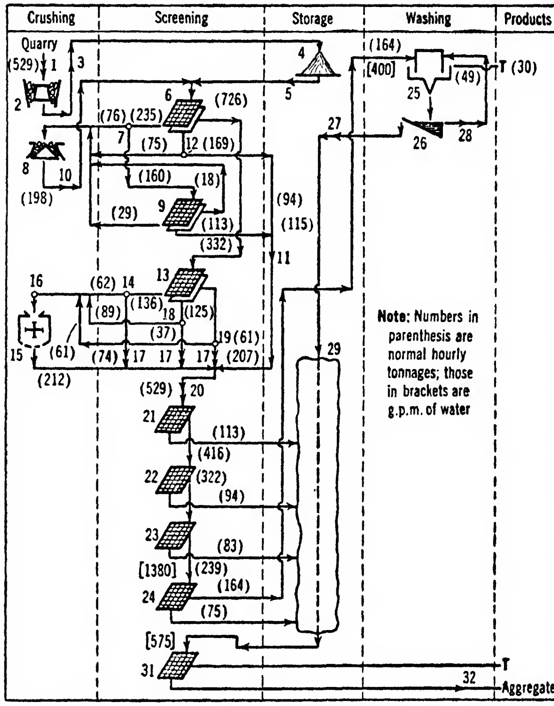
23. 2 FB-4 Jeffrey-Traylor magnetic-vibrator screens, 3/4-in. aperture.

24. 2 @ 4×10-ft. Symons shaking screens, 7/32-in. openings.

25. 1 @ 13-ft. Auto-Vortex bowl classifier; underflow, 40 to 45% solids.



26. 1 @ 12-ft. Dorrco washer.

27. Belt conveyor H; Barber-Greene radial sand stacker.

28. 1 @ 6-in. Wilfley pump throttled to 3 1/2 in.

29. Ground storage, served by a timbered conveyor tunnel 600 ft. long under center; 2 @ 24-in. hand-operated gates for each size of rock and 8 for sand; 1 @ 24-in. reclaiming belt in tunnel.

30. Contains about 1% >10-m. sand.

31. 2 @ 4×14-ft. Low-head screens with 3/16× 1-in. staggered slots in 3/16-in. plate; first 4 ft. sprayed; compressed air blowing at discharge end necessary to complete drainage of fine rock.

32. Belt conveyor to mixing plant.

FIG. 74. TENNESSEE VALLEY AUTHORITY, Hiwassee Dam plant.

Summary. Three-stage crushing, with size-distribution control in the second and third stages by splitter recirculation of excess sizes to the crushers. Grading of crushed product into four stone and one sand size by series (as opposed to pyramid) screening and classifier washing in series. Some control of sand-size distribution by variation in load on the two third-stage crushers. All products rinsed out of storage.

Screen capacity is said to be higher than in the NORRIS DAM plant, where pyramid screening (sending a long-range feed first to an intermediate or even the final screen of a series), apexed on the 3/4-in. screen, overloaded it and the following 1 1/2-in. screen with oversize. Also the 4-m. screen at NORRIS was run dry.

Fontana Dam aggregates plant, Fig. 75 (*46 #9 RP 49*).

Location: 35 mi. S.E. of Knoxville, Tenn.

Capacity: 800 t.p.h.

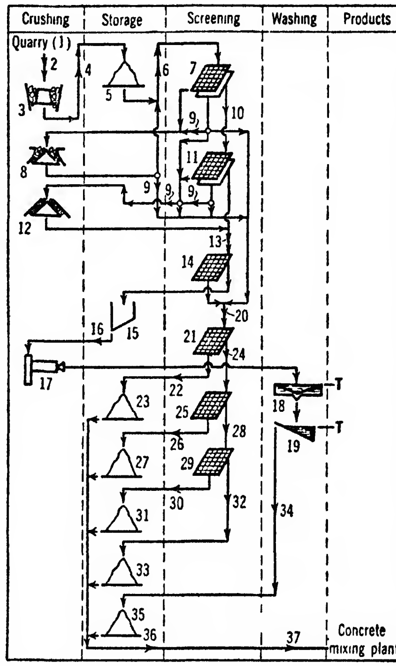
Stone: Quartzite (rather hard), about 80% SiO_2.

Site: A narrow valley of the Little Tennessee River; quarry and primary-crushing plant on one side of river and screening and washing plant on other.

Summary. Two-stage crushing for rock with scalping screens to control amount of secondary crushing; one-stage crushing and open-circuit rod milling for stone-sand. Rock from crushing plant combined and rescreened in rock-grading plant. Rock blended out of storage; sand drawn separately on same reclaiming belt.

Legend for Fig. 75:

1. 3-cyd. shovels.
2. Fleet of 10- and 12-cyd. trucks to crushers at one end of quarry floor.
3. 2 @ 42-in. Superior gyratory crushers, 6-in. open setting.
4. 1 @ 5×9-ft. Jeffrey-Traylor vibrating feeder; 1 @ 42-in. belt conveyor on suspension bridge across river (900 t.p.h.).
5. 1 @ 10,000-ton live, 35,500-ton total stockpile.
6. 1 @ 4×8-ft. magnetic-vibrating feeder; 1 @ 42-in. belt conveyor (800 t.p.h.).
7. 2 @ 5×12-ft. Ty-rock screens in parallel; 6×7 1/2-in. plate and 3 1/4-in. woven-wire surfaces.
8. 2 @ 4 1/4-ft. standard cone crushers (380 t.p.h.).
9. Alternative.
10. 1 @ 36-in. belt conveyor (654 t.p.h.).
11. 2 @ 5×12-ft. Ty-rock screens in parallel, 1 5/8- and 3/4-in. apertures.
12. 2 short-head cone crushers.
13. 1 @ 30-in. belt conveyor (396 t.p.h).
14. 2 @ 6×14-ft. Riplflo vibrating screens; screen aperture varied from 1/4-in. to 3/4-in. according to demand.
15. 1 @ 500-ton surge bin; 2 Syntron feeders.
16. 2 @ 24-in. belt conveyors (131 t.p.h. ea.).
17. 2 @ 9×12-ft. A-C rod mills in parallel; 75,000 lb. @ 3 1/2; 3-, and 2 1/2-in. high-carbon steel rods (3 1/2-in. replacements), 0.6 to 0.7 lb. per ton of feed (= 0.7 to 0.8 lb. per ton of sand produced); manganese-steel liners, 1 @ 800-hp. motor with V-belt drives to the 2 mills. For grind see Table 31.
18. 1 @ 16×5-ft. hydro-bowl classifier (see Table 31).
19. 1 @ 5×30-ft. and 1 @ 7×30-ft. rake classifiers in parallel (see Table 31).
20. 3 @ 36-in. belt conveyors in series (537 t.p.h.).



21. 2 vibrating screens, 3 1/4-in. aperture.
22. 2 Barber-Greene stacker conveyors.
23. 17,000-ton stockpile (7,000 tons live).
24. 1 @ 30-in. belt conveyor (146 t.p.h.).
25. 2 vibrating screens, 1 5/8-in. aperture.
26. As (22).
27. As (23).
28. 1 @ 24-in. belt conveyor (245 t.p.h.).
29. 2 vibrating screens, 7/8-in. aperture.
30. 2 as (22).
31. 13,500-ton stockpile (5,100 tons live).
32. 1 @ 24-in. belt conveyor (123 t.p.h.); 1 Barber-Greene stacker.
33. 13,500-ton stockpile (5,800 tons live).
34. 2 @ 30-in. belt conveyors; 1 @ 30-in. stacker (231 t.p.h.).
35. 30,000-ton stockpile.
36. 1 @ 36-in. tunnel conveyor under all stockpiles.
37. 1 @ 36-in. suspended conveyor over river; 2 @ 5×14-ft. Symons screens for rinsing rock (only).

FIG. 75. FONTANA DAM aggregates plant.

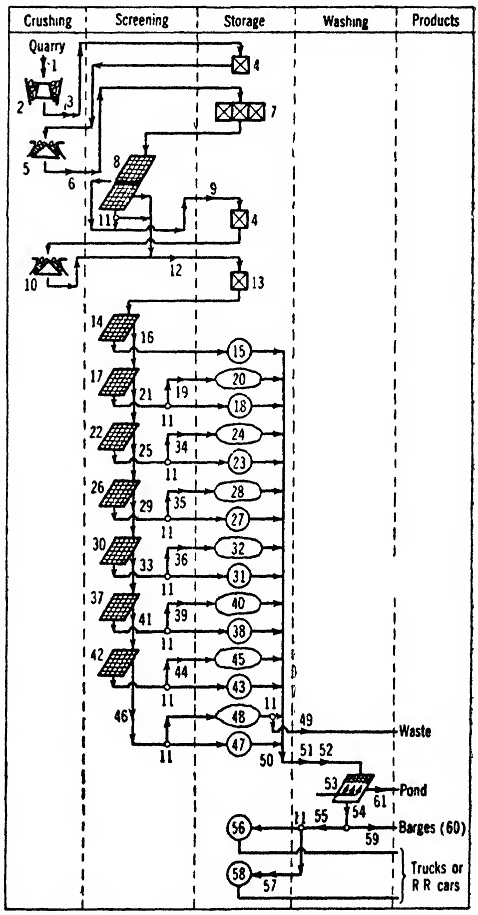
New York Trap Rock Corp., Fig. 76 (*33 #26 RP 26; 21 #7 PQ 72*).

Location: Clinton Point, N. Y.
Capacity: 800 to 1,000 t.p.h.
Crude: Trap rock.
Products: 8 sizes: 3 1/4~2 1/2-in., 2 1/2~1 1/2-in., 1 1/2~1 1/4-in., 1 1/4~1-in., 1~3/4-in., 3/4~5/8-in., 5/8~1/4-in., 1/4~1/8-in.
Power: 4,056 connected hp.; about 65% drawn at full capacity. Current comes in at 66,000 volts,

3-phase, 60-cycle; transformed to 23,000 volts for distribution; motors, 440-v. for 25-hp. and smaller, 2,300-v. for larger sizes.

Site: Crushing plant steeply sloping; screening, storage, and washing level. Plant on both sides of N. Y. Central main-line tracks on east bank of Hudson River about 50 mi. from New York City (Fig. 77).

Buildings: Steel and concrete. See Figs. 77 to 86.



Legend for Fig. 76:

1. 7 1/2-ton 5-cyd. side-dump trucks on quarry floor; aver. haul, 750 ft.; 12 trucks can make 240 dumps per hr., aver. is about 100. Trucks are dumped by a hoist-controlled frame on an incline, provided with dependent hook which engages an eye on the truck body.

2. 1 @ 21-in. A-C gyratory crusher, in 40-ft. pit below dumping level, 9-in. open set; 250-hp. motor served by a 40-ton crane with 10-ton auxiliary hoist carrying a disengaging hook for stuck rock.

3. Conveyor, Table 32, see Figs. 77, 83.

4. 3 @ 20(deep) × 16 × 15 1/2-ft. reinforced-concrete surge bins (item *a*, Fig. 79); the 3 @ 42-in. apron conveyors *b* on tracks over cones (5) and (10) roll back to facilitate cone repairs.

5. 1 @ 7-ft. cone crusher, 3-in. set (Fig. 79).

6. Conveyor, Table 32 (Figs. 78, 79).

7. 1 @ 6-compartment 700-cyd. concrete bin (item *a*, Fig. 80); 6 @ 36-in. apron feeders (item *b*, Fig. 80).

8. 4 @ 4 × 20-ft. rotary scalping screens (Fig. 80), 3 1/4- and 2 1/8-rd. apertures; 2 @ 4 × 8-ft. single-deck vibrating scalping screens, same apertures.

9. Conveyor, Table 32 (Figs. 78, 80, 83).

10. 1 as (5), 2-in. set.

11. Alternative.

12. 2 conveyors in series, Table 32 (Figs. 78, 80, 83).

13. 1 @ 40-cyd. surge bin (item *a* of Fig. 81, and Fig. 82); 2 @ 36-in. apron feeders (item *b*, Fig. 81).

14. 4 @ 4 × 10-ft. Gyrex screens (Fig. 81), 2 1/2-in. manganese-steel-wire cloth.

15. 1 @ 50(diam.) × 80-ft. reinforced-concrete silo (Fig. 82).

16. 2 conveyors in parallel, Table 32 (Fig. 82).

17. 4 as (14), 1 1/2-in. aperture (Fig. 82).

18. 1 as (15) (Fig. 82).

Fig. 76. New York Trap Rock Corp.

Legend for Fig. 76—Continued:

49. Excess over market by conveyor 48 (Table 32) to loading bin and thence by truck to a depression behind quarry where it is available for reclamation.

50. 5 gates under each silo and 5 under each open-storage pile (Fig. 82); dead-stored material in open piles dragged to gate hoppers by a 1 1/2-cyd. crawler dragline crane with 80-ft. boom.

51. Tunnel conveyor, Table 32 (Figs. 82, 83).

52. Conveyor, Table 32 (Figs. 83, 84).

53. Screen washer (Fig. 84), comprising 5 steps of fixed screens (1/8- or 1/4-in. apertures) with high-pressure (60-lb.) sprays; 60-ft. fall, 407 sq. ft. of screening surface.

54. Reversible conveyor, Table 32 (Figs. 83, 84). Feeds at one end to (55) and at the other to (59) (Fig. 83).

55. Conveyor, Table 32.

56. 20(diam.)×60-ft. reinforced concrete silo on loading track (Fig. 85).

57. Conveyor, Table 32; traveling tripper (Fig. 85).

58. 7 as (56) in parallel therewith (Fig. 85); (56) and these load out through side arc-type drop-chute gates to cars (one side) or trucks (other side); 20-ton truck scale, 100-ton track scale.

59. Conveyor, Table 32 (Figs. 83, 86).

60. 850- to 900-ton; loaded in 40 min.; take bulk of shipments (Fig. 86).

61. 8-in. centrifugal pump, 1/2-mi. to 10-acre pond; sluiceway for clear water to river; river salts aid clarification.

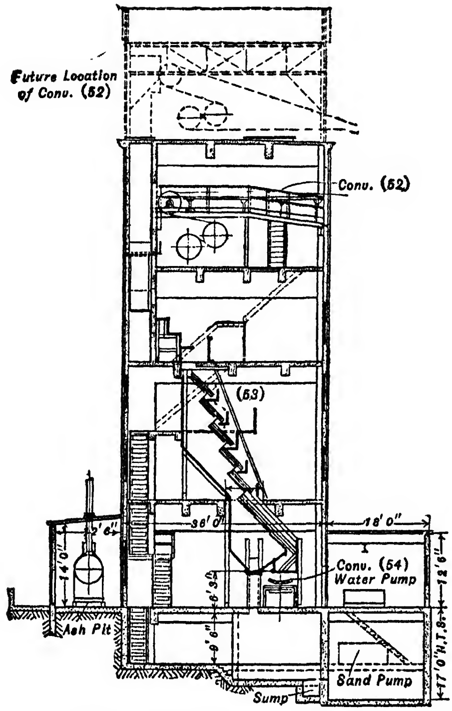

Fig. 84. Wash house; plant of Fig. 76.

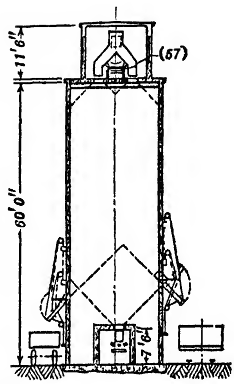

Fig. 85. Car- and truck-loading silos; plant of Fig. 76.

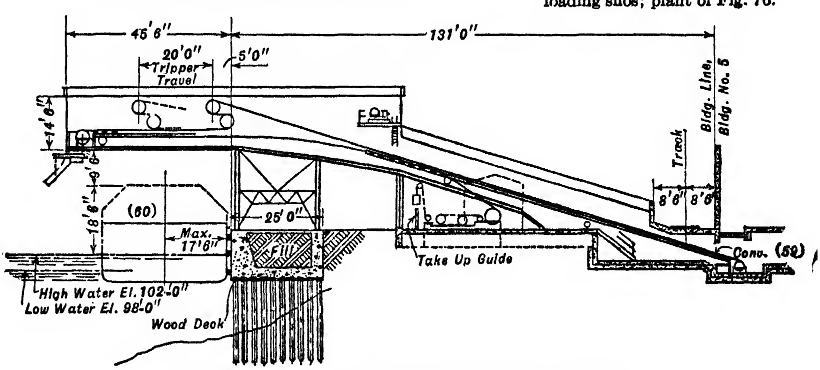

Fig. 86. Arrangement for barge loading; plant of Fig. 76.

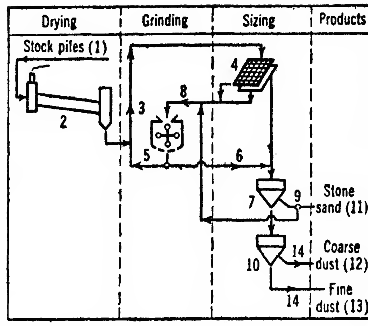
Summary. Three-stage crushing in gyratory and 2 cone crushers in series, the second cone operating in open-, partly closed-, or closed-circuit, as desired, with a 2 $^1/_2$-in. screen. Crushed product closely sized to 8 grades from $<3\ ^1/_4$-in. to $^1/_8$-in. and stocked. Shipments drawn from stock as wanted, washed, and sent to loading bins for land shipment or to barges.

Dolese and Shepard Co., Fig. 87 (*41 #6 RP 39*).

Location: La Grange, Ill.
Capacity: 15 to 17 t.p.h.
Crude: Limestone chip ($^5/_8$~$^1/_4$-in.) and $<^1/_4$-in. screenings.
Products: Stone sand; coarse and fine dust.
Power: 130 kw. total, average.

Legend for Fig. 87:

1. Separate stockpiles of the two crudes, about 5 1/2% water; 2 1/4-cyd. clamshell bucket; hopper; 50-ft. belt conveyor.
2. 1 @ 6×60-ft. rotary drier, 4 1/2 r.p.m., coal-fired, 270° F., 1 3/4 tons per 8 hr. of 4-in. lump bituminous.
3. Elevator.
4. 1 @ 4×10-ft. 2-deck vibrating screen, 4-m. and 8-m. apertures.
5. Gruendler ring-roll crusher, 1/16-in. bar spacing.
6. Elevator.
7. 1 @ 14-ft. Raymond air sizer.
8. Surge bin.
9. Splitter.
10. 1 @ 10-ft. double-cone Raymond air sizer.
11. 98% <8-m., practically dust-free, 77 t.p.d. Coarser and cleaner with chip feed to plant than when screenings are fed.
12. 75% <100-m., 7 t.p.d.



13. 93% <200-m., 28 t.p.d.
14. Bagging machine.

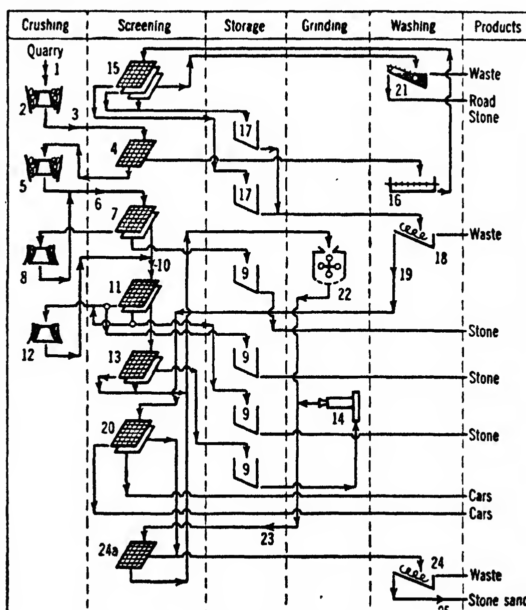
FIG. 87. DOLESE AND SHEPARD CO.

Summary. Dry-process stone sand and dust by drying and hammer-milling in closed-circuit with screens and an air sizer.

Radford Limestone Co., Fig. 88 (*41 #4 RP 34*).
Location: East Radford, Va.
Capacity: 2,000 t.p.d. coarse aggregate stone sand.
Crude: Dolomitic limestone.
Products: Aggregate, 3 1/2~1 1/2-, 1 1/2~3/4-, and 3/4~3/8-in.; washed stone sand, 95% <4-m.; 60 to 75% <16-m., 15% <100-m.; washed fine (<3/16-in.) road stone.

Legend for Fig. 88:

1. Side-dump cars, steam locomotive.
2. 1 @ 42-in. Superior McCully gyratory crusher; 250 t.p.h.
3. 1 @ 36-in. belt conveyor.
4. 1 @ 5×20-ft. revolving stone screen, 1 3/4-in. aperture.
5. 1 @ No. 8K A-C gyratory crusher.
6. 1 @ 30-in. belt conveyor.
7. 1 @ 5×12-ft. 2-deck Niagara screen, 3 1/2-in. and 1 1/2-in. apertures.
8. 1 @ 10-in. Superior reduction gyratory.
9. Storage bin.
10. 1 @ 30-in. bucket elevator.
11. 1 @ 4×14-ft. 2-deck Niagara screen, 3/4- and 3/8-in. apertures.
12. 1 @ No. 25 and 1 @ No. 19 Kennedy gearless crusher, and 1 @ 20-in. Traylor TY reduction gyratory in parallel.
13. 1 @ 4×8-ft. 2-deck Aero-Vibe screen, 5/16- and 3/16-in. openings.
14. 1 @ 6×10-ft. rod mill.
15. 1 @ 3×10-ft. 3-deck Niagara screen, with 60-lb. spray nozzles; 3/4-in., 3/8-in., and 3/16-in. apertures.



16. Puddler.
17. Soaking bins; retention about 1 hr.
18. 1 @ 20-in. double-screw Link-Belt washer.
19. Bucket elevator, 30-ft. centers.
20. 1 @ 3×8-ft. Nordberg vibrating screen.
21. Sand drag.
22. 1 @ No. 7 Maxecon-Kent mill and 3 @ No. 2 Sturtevant ring-roll mills in parallel.
23. 1 @ 56-ft. bucket elevator.
24. 1 as (18).
24a. Vibrating screen, 3/8-in. aperture.
25. 120-ton steel bin.

FIG. 88. RADFORD LIMESTONE CO.

Summary. Primary crushing to about 6-in.; scalping at 1 1/2-in.; undersize scrubbed, washed, and sized with <3/16-in. rejected; oversize crushed in two stages; excess gravel sizes further crushed and joined with fines for further grinding, screening, and washing to make stone sand.

42. SULPHUR

Properties. Native sulphur (BRIMSTONE) has a distinctive yellow color which may be darkened by impurities; streak is white; luster, resinous; fracture, conchoidal to uneven: hardness, 1.5 to 2.5; sp. gr., 2.05; it is translucent to opaque; melts at 234° to 248° F., depending upon the crystalline state, to a dark amber liquid which boils at 832° F. It ignites in air at 478° F., burning with a distinctive blue flame and evolving SO_2, an unmistakable test. Sulphur conducts heat and electricity poorly. It is insoluble in water, acids, and most liquids other than carbon disulphide, carbon tetrachloride, and the heavier liquid hydrocarbons. If boiling sulphur is quenched suddenly it becomes rubberlike but reverts to crystalline form in a few days. It has other allotropic modifications.

Uses. The largest single use of sulphur is for production of sulphuric acid, the leading domestic uses of which, in turn (*44 CME 78*), were (1936): fertilizer manufacture (20%), oil refining (16%), heavy chemicals (13%), coal products (11%), iron and steel pickling (10%), other metallurgical uses (8%). Large quantities are used also in making paints, explosives, rayon and cellulose films, textiles, sulphite pulp, rubber manufacture (3%), insecticidal dusts and sprays and other agricultural outlets, and for numerous other minor purposes. An excellent pouring cement can be made from molten sulphur and sand, Portland cement, or other aggregate; one of the strongest being 40% S and 60% sand. Pyrite cinder is a valuable source of iron. Principal uses for pyrites are in making sulphuric acid and sulphite wood pulp. Lump ore is burned in deep beds on grates about 5 × 5 ft. much like coal. Fines or "smalls," formerly unsalable, are now roasted in cylindrical multiple-hearth furnace of McDougal type. Latest development is "flash-roasting" of air-floated dust in vertical combustion chamber (*216 CIMM 471*). Pyrite may be a source of elemental sulphur and is also used as source of iron or sulphur or both by smelters but usually such ores contain gold, silver, and perhaps base metals and are not purchased directly as pyrite. Minor uses are in radio crystals, jewelry, and in manufacture of iron pigments.

Occurrence. The primary sources are native sulphur and iron pyrite. Normally, 95% or more of the world's native sulphur comes from sedimentary deposits in which it occurs as irregular masses associated with calcite, dolomite, gypsum, anhydrite, and usually bituminous matter, with occasionally a little barite or celestite. The bedded Sicilian deposits produce a crude with average rock content around 17%. In the Gulf Coast deposits the sulphur occurs in the cap rock overlying salt domes, at depths of 450 to 1,500 ft., generally topped with a cap of anhydrite or anhydrite-calcite layers. They are circular or elliptical in cross-section and range in area from a few to several thousand acres. Thickness of the sulphur in a given deposit ranges from a few inches to 100 ft. The sulphur content may be 50%, but the average is probably not much over 20%. The first such deposit developed (at Sulphur, La.) yielded about 10,000,000 tons of sulphur from 1902 to exhaustion in 1924.

Pyrite occurs widely distributed and abundantly in veins, disseminated deposits, in coal seams, and as masses in contacts. Marcasite is less abundant. Pyrrhotite forms large deep-lying masses in metamorphic rocks, usually near contacts with granite. Pyrrhotite bodies containing copper and/or nickel and platinum-group metals are worked at COPPER CLIFF (Sec. 2, Fig. 144), NORANDA (Sec. 2, Fig. 37), POTGIETERSRUST (Sec. 2, Art. 37). Massive pyrite deposits carrying copper are worked at TENNESSEE COPPER CO. (Sec. 2, Fig. 38) and RIO TINTO; other deposits high in pyrite, the ores of which are treated to recover pyrite as well as other values, are ANACONDA (Sec. 2, Fig. 21), ALDERMAC (Sec. 2, Fig. 30), MIDVALE (Sec. 2, Fig. 124), BALMAT (Sec. 2, Fig. 115), TREPCA (Sec. 2, Fig. 114), etc.

Production. Seven domes in the United States Gulf Coast region now supply about one-third of the world's sulphur and fully two-thirds of the world's production of elemental sulphur, including that recovered in the treatment of pyrite, smelter fumes, and gas manufacture. One dome has yielded 3,000 tons daily for many years. Shipment from American mines for domestic and export consumption averaged 2,104,586 long tons in 1925–29 and rose to a new peak of 2,466,512 long tons in 1937; Texas furnishes 75 to 80% and Louisiana most of the remainder. Italy normally produces 300,000 to 400,000 tons a year. World production of pyrite grew from about 6,000,000 tons in 1900 to 8,000,000 tons in 1929; the estimated sulphur content increased, however, only from 2,704,524 to 3,130,420 metric tons. Spain for many years furnished 50% or more of the world total. Since 1930 production of pyritic sulphur in Japan, Norway, Italy, U.S.S.R., Germany, Finland, and Great Britain increased rapidly, and since 1932 consumption of pyrite in the United States has recovered faster than that of brimstone; domestic production rose to a new peak of 584,166 long tons valued at $1,777,787 in 1937; Tennessee was the leading state, other producers being California, Colorado, Illinois, Kansas, Missouri, Montana, New York, Virginia, and Wisconsin.

Selling. The average price of crude sulphur, f.o.b. mines, during 1925–29 was $17.50 a long ton. In addition to crude, the United States produces treated forms such as crushed, ground, refined, and sublimed sulphur, and flowers of sulphur; exports under this general category have recently averaged $35 to $40 a ton. Sulphur from the Frasch process is guaranteed 99.5 and often runs 99.8% S; it is free of As and Se. Italian sulphur is graded according to content of various inorganic impurities. Chief specifications for flour sulphur cover particle size but the rubber industry further specifies under 0.01% free acid.

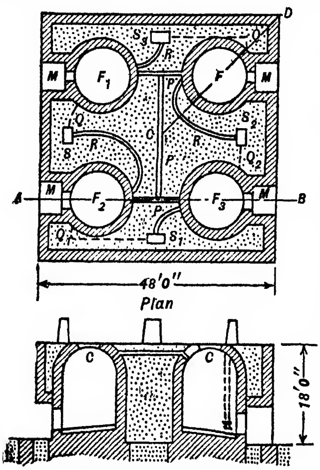


FIG. 89. Gill furnace.

Specifications for pyrite are usually determined by agreement under long-term contract, since each ore has its own peculiarities. Along the Atlantic seaboard Spanish pyrite has been quoted generally at 12 to 13¢ per long-ton unit of contained S. Often sellers contract to take back the cinder. Washed Spanish pyrite contains 48 to 50% S and less than 0.5% Cu, but ordinary Spanish pyrite (CUPREOUS) contains around 47% S and almost 2% Cu. Lump ore ranges in size from 2- to 10-in.; not over 10% should pass 1/2- or 3/8-in. screen. Contracts usually call for a penalty when S content falls below a specified percentage. Zinc and lead are always undesirable. Arsenic over 1% is objectionable for acid manufacture and selenium is objectionable for paper-making. Most of the domestic pyrite is consumed by producing companies. Domestic output was valued at $3.78 per long ton in 1913, $3.75 (average 36.1% S) in 1929, and $3.05 (39.7% S) in 1937, f.o.b. mines.

Treatment. Recovery of native sulphur from the associated rock depends upon the relatively low melting point of sulphur (246° F.) and the relatively high fluidity of the orthorhombic allotrope. Methods of recovery from high-grade products involve simply heating the mixture to a temperature between the melting point and the temperature of inversion (1 1/2° F.) and flowing the liquid sulphur away from the nonmolten associates.

Sicilian sulphur, which is mined in a relatively rich state, is melted by the heat generated in burning a part of the sulphur. The Gill furnace (Fig. 89), normally used for the operation, is a compartmented furnace, normally with 5 or 6 cylindrical domed chambers or compartments F, each with a bottom sloping toward a draw-hole. The furnaces are charged by first placing a layer of 12- or 14-in. lumps of limestone on the floor, so arranged as to leave ready channels to the draw-hole, to charge at the center of this base coarse lumps (5- to 10-in.) of crude sulphur in a heap about 3 or 4 ft. in diameter, and then to fill the remainder of the chamber with the finer material (total charge about 30 tons). Flues P, with suitable dampers, connect the various compartments, and other flues Q and R run to chimneys S. A cycle comprises the use of 3 chambers, *e.g.*, air for combustion enters, say, F, which has been burned and is filled with hot slag; the air is heated in passing over the slag and flows thence through P to the top of F_1, operated down-draft, and ignites the top of the charge therein. The combustion gases passing down through the charge in F_1 melt sulphur, and then pass out through bottom flue Q, upward through S and thence, in part, through R and into F_2, downward through the charge in F_2, preheating it, and finally discharge to the atmosphere through Q_1 and S_1. Cycle time on a 30-ton 4-compartment furnace is about 20 days. Recovery in modern forms is about 80% (*30 IEC 742*), the balance being lost by combustion. First-grade product is about 99.5% S; the least pure grade is about 96%.

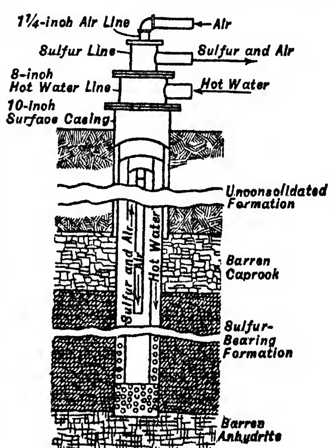

FIG. 90. Frasch-process well.

Frasch process uses water heated under pressure to a temperature upward of 250° F. to melt the sulphur in place underground and to transport it to the surface, where it settles and solidifies in large vats in a high state of purity, and is therefrom mined for shipment, after the walls of the vats have been removed. The essential parts of the apparatus are the wells and piping shown in Fig. 90, the requisite water heaters, compressors, and air

heaters, surface piping and vats. Hot water is pumped down the well at 150 lb. pressure, percolates out through the surrounding rock from the upper holes, and returns with molten sulphur through the lower holes, and thence upward as indicated, lightened by impregnation with heated air. The difficulties involved in the operation are financial and mechanical. A large and costly plant is required; and much H_2S is associated with the sulphur, with corresponding corrosion troubles.

The large size and high purity of the Louisiana-Texas sulphur deposits, the low cost of production, and the accessibility to ocean transport make this sulphur dominant in the world market in so far as dealings are not controlled by politics.

Chilean sulphur (*49 MM 137*) is hand sorted at the pits to about 60% S, and retorted in horizontal retorts charged from heated hoppers above. The sulphur vapors pass from the retort into condensing chambers, which are small when lump sulphur is to be made and large for the sublimed form. Product is 99.5 to 99.8% S. The lump sulphur is ground in fixed-path mills (Sec. 6, Art. 2) with built-in or external separators, using a neutral atmosphere.

Low-grade crudes can be enriched by flotation (Sec. 12, Art. 54) to concentrates assaying 75% S or higher, but not to a point of salable purity. Such concentrate is usually refined by melting in autoclaves with water when, if the droplets do not become coated with the finely divided rock-forming mineral, the melted sulphur runs together and can be flowed out and solidified in an acceptably purified form. Extraction with organic solvents, *e.g.*, CS_2, has also been used for final purification.

Treatment of pyrite. In Spain, ore averaging 48% S and less than 1 1/2% Cu is marketed with no treatment other than screening. Ore containing over 3% Cu is smelted or used to recover elemental S; intermediate grades are leached in heaps for 2 yr. At Ducktown, Tenn., some crude ore is still smelted directly for copper, sulphur gases being sent to acid plant but nowadays the major portion is treated by selective flotation and pyrite concentrates roasted in Herreshoff furnaces, calcines from which go to Birmingham iron and steel manufacturers. In Wisconsin and occasionally elsewhere table concentrates have been lightly roasted and pyrite separated from sphalerite of like specific gravity magnetically. The recent trend is selective flotation, which may increase supplies of by-product pyrites. Coal-washing is also a source of pyrite, especially in Kansas and Illinois.

By-product sulphur may be made from smelter smoke, in purifying manufactured gas, and, of course, from pyrite. At CONSOLIDATED M. & S. Co., Trail, B. C. (*45 CME 483*), dust-free roaster gas is absorbed in wood-slat trickle towers in aqueous ammonium sulphite, thereby changing the sulphite to bisulphite, temperature being held below 40° C. Absorbing capacity is kept up by bleeding off bisulphite solution at a concentration of 5 to 6 lb. SO_2 per gal. and adding aqua ammonia. Solution is filtered through plate presses and then acidified with concentrated H_2SO_4 which, with steam, drives off SO_2 and forms ammonium sulphate. The SO_2 is dried with concentrated H_2SO_4 and reduced with coke. The resulting product is 99.99% S. Ammonium sulphate is a by-product.

43. TALC AND SOAPSTONE

Properties. Talc is commonly assigned the formula $H_2Mg_3(SiO_3)_4$ but its composition varies; even the MgO content may range from 27.9 to 32.4%. Color is white, greenish, or grayish; luster, pearly; hardness, 1; readily sectile; sp. gr., about 2.7. When heated, talc gives off about one molecule of water between 715° and 930° F. without changing its physical structure. Another molecule (combined water) comes off between 1,470° and 1,540° F., absorbing much heat, and initiating inversion to glass-hard enstatite, or clinoenstatite, and SiO_2. It fuses around 2,000° F. The crystal structure is almost identical with that of pyrophyllite. Compact talc (often called STEATITE, though this is strictly the name of a rock) grades into SOAPSTONE, which is a general term for massive material, and covers not only that consisting chiefly of talc but other metamorphic rocks that are soft and greasy in texture. Talc and soapstone both have good electrical properties, resist the action of most acids and alkalies, and have an extraordinary capacity for retaining heat.

Commercial talc is a mixture of talc with other minerals; it is classified into hard and soft, fibrous and flake, and by screen size and color. Fibrous talc owes its structure mainly to tremolite; gritty talcs usually contain dolomite or magnesite; dark-colored talcs are likely to contain admixed serpentine or chlorite; flake and soft talcs only are relatively pure talc.

Uses. The paint industry is the principal outlet for ground talc, soapstone, and pyrophyllite, consuming about one-quarter of total domestic sales; the ceramic industry took 13% in 1937 and ranked as the third consuming industry; paper took 14%, rubber 12%, and roll roofing 10%; consumption for toilet preparations and foundry facings are much less important. Relatively small quantities are consumed as fillers in various articles; as polishes for rice, peanuts, and glass, and in lubricants, concrete, plaster, and insecticides. Soapstone or talc crayons (French chalk) are used chiefly for marking cloth and glass, and LAVA (calcined talc) either massive or compounded with silicate of soda (ALSIMAG) or other binder is used in gas-burner tips and for numerous electrical and refractory specialties. Sawed soapstone slabs are used in laundry tubs, laboratory benches, and various structural purposes, but the largest single use is in refractory blocks for smelting sulphate (KRAFT) pulp.

Occurrence. Commercial deposits of talc and soapstone are found only in much altered, old ultrabasic intrusions, or in certain metamorphosed dolomitic limestones. In Vermont the deposits lie in a serpentine belt that yields asbestos farther north; but near Schuyler, Va., soapstone occurs in large sheetlike bodies that were altered progressively into chlorite and finally talc without being serpentinized. Certain European deposits, including some of those that yield the best grade of toilet talc, occur in lenses and irregular masses interbedded with crystalline schists. Some of the best talc and some of the largest deposits occur in dolomites intruded by igneous rocks. Accessory minerals in commercial talcs, usually left in the final product, include serpentine, dolomite, magnesite, calcite, and tremolite with occasional chromite, magnesite, and traces of nickel and other constituents of basic rocks.

Production. Talc and soapstone are so widely distributed in nature that most industrial countries produce some for their own needs, but the United States usually produces about one-third of the world total and two or three times as much as any other country. Manchuria recently has vied with France for second place, followed by Italy, Norway, Austria, Canada, and India.

Domestic production of pyrophyllite, talc, and ground soapstone rose in 1937 to 229,999 short tons, well above the general level of 210,000 to 220,000 that marked the upper limit of sales during the previous 20 yr. Of this quantity 217,811 tons was ground, 1,101 tons was sawed or manufactured, and 11,087 tons was sold crude, much of it probably to be ground later. In addition a substantial quantity of soapstone slabs and blocks was produced in Virginia and sold as dimension stone.

Selling. The average value per ton of all grades of talc, pyrophyllite, and ground soapstone, f.o.b. mills, dropped from $12.50 to $10.43 per short ton in 1928 and rose to $11.14 in 1937. Prices of imported talc range from $10 to around $80 per ton. Manchurian talc sells in the United States for $30 to $40 per ton, a little off-color material fetching $20. Italy sells various grades, but that shipped to the United States costs around $30 to $40 per ton, f.o.b. mines, and is priced delivered to American wholesale consumers at $45 to $80 per ton. Ground soapstone is generally quoted around $5 per ton for 200-m. and up to $7 per ton for 325-m., f.o.b. Virginia plant. Roofing talc, 20∼50 m., sells as low as $4, while the poorer grades ground through 200-m. fetch $8.50 per ton or more in bulk, $1 extra in bags. New York fibrous talc (ASBESTINE) ground through 325-m. for the paint trade normally sells for $12 to $15 per ton, occasionally much higher. High-grade LAVA TALC, lumps, may sell for as much as 6¢ per lb., and the various forms of sawed talc generally sell for at least $100 to $150 per ton.

Treatment. Massive talc that may be taken out in lumps is scabbed with an axe to remove adhering impurities and then sawed like cordwood into smaller pieces so as to facilitate cutting out hard particles and fibrous material. Sometimes it is further shaped by expert machinists into articles which are heated gradually up to 1,800° F., kept at this temperature for 6 hr., and cooled in the furnace for 24 hr., becoming harder than steel. Soapstone is shaped and surfaced like marble, but more easily (*IC 6563*).

About 95% of the total tonnage is milled. Wet-grinding, as a means of avoiding dust-disease hazard, is already employed at Hemp, N. C., for pyrophyllite; but dry-grinding followed by air separation is universal practice, except for cosmetic talc, which is bolted through cloth. In only a few mills is preliminary drying needed. For fine grinding, Raymond, Hardinge, tube, emery, attrition, and buhr mills are all used (see Sec. 6). Roofing granules are made by SEABOARD OPERATING Co., Marriotsville, Md., in a hammer mill followed by Sturtevant buhrstone mill and screens, whereas ALBERENE STONE CORP., Schuyler, Va., uses a hammer mill for secondary crushing (from about 1 in. to $^1/_4$ in.) and ball mill for fine grinding; coarser products (main tonnage 40∼48-m.) are sized on Hum-mer screens and fines are air-classified to 97% <300-m. Flotation is used by EASTERN MAGNESIA TALC (Fig. 92); it yields much better and purer product (tailing may be sold as low-grade magnesite) but does not improve slip sufficiently to compete with best Italian, Spanish, and Manchurian talcs. Elsewhere no concentrating is done except that which results from selective grinding; by using a throw-out attachment on the grinding mill or an air separator it is possible to leave most of the grit in a coarser product that may be marketed to the roofing trade, the relatively pure fine-ground product being sold for paper making and other uses. Flotation permits close control of the ratio of talc to subsidiary mineral in commercial products. Tests on Gouverneur, N. Y., talc (*18 ACerS 292*) showed that ores containing fibrous talc and those containing tremolite and calcite were much more difficult to separate than those containing foliated talc and quartz. Different flotation agents were required for the various ores; pine oil was suitable for foliated talc, but amine-type reagents were better for fibrous talc. Tremolite-enriched tailing from talc-tremolite ores need not be thrown away, being usable in wall-tile mixtures.

Southern Talc Co., Fig. 91 (*143 #11 J 45*).

Location: Murray Co., Ga.
Crude: Gray opaque talc, unsuitable for cosmetics.
Products: Principally crayon, and ground for filler and surfacer for asphalt roofing, paper, and shingles.

Legend for Fig. 91:

1. Sledging floor.
2. Williams Jumbo No. 1 hammer mill, 25-hp. motor.
3. Elevator; 50-ton bin.
4. Williams 4-roll crusher, 60-hp. motor on mill, 40-hp. motor on fan; a = grinding ring; b = built-in air classifier. Electric-eye control of feed operated by a colored-water column actuated by back-pressure in the mill.
5. Williams vibrating screen, aperture as desired.
6. Cyclone collector.

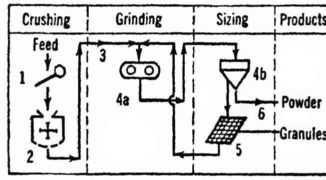

FIG. 91. SOUTHERN TALC Co. (grinding mill).

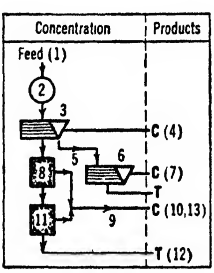
Summary. Selective mining to separate crayon and grinding stocks. Crayon stock sawed; rejects to grinding stock. Latter is crushed in a hammer mill and ground in a fixed-path dry grinding mill (Sec. 6, Art. 2) with built-in air separator.

Sawing is done on a saw line comprising a line of saw tables about 42 in. high and 42 in. wide with saws projecting upward through top. Material progresses along the table from saw to saw manually. Order of saws is: 24-in. facing saw, producing roughly square blocks; 14-in. blocking saw, producing blocks about 5 in. long (crayon length); 2 @ 14-in. stocking saws, cutting to crayon thickness (1/4 to 3/16 in.); 7 @ 9-in. pencil saws, with individual operators, cutting to crayon widths (1/4 to 1/2 in.). Round pencils are made from 1/4-in. square crayons by pushing these individually through a rounding machine. All saws are push-button controlled. A crew of 10 men on the saw line cuts 450 to 800 gross of crayons per 8 hr. (150 to 200 gross per ton of saw rock).

Eastern Magnesia Talc Co., Fig. 92 (*32 #4 PQ 28*).

Location: Burlington, Vt.
Capacity: 1.2 t.p.h.
Crude: Air-classifier reject from dry grinding; contains 55% talc, 35% magnesite, and small quantities of Ni and Co minerals.
Products: Nickel concentrate; 95% talc; a low-grade magnesite (90% $MgCO_3$).



Legend for Fig. 92:

1. Air-separator reject from dry grinding; screw feeder; conical storage tank with Syntron feeder.
2. Denver conditioner; reagents and water added. Reagents (*RI 3314*) are pine oil, kerosene emulsified by Emulsol X-1, sodium silicate ±Calgon.
3. 2 shaking tables (Wilfley, Plat-O).
4. 18 to 24% Ni.
5. Middling contains 80% $MgCO_3$, 15% talc, 5% Ni.
6. James table.
7. 18 to 22% Ni, 2% Co.
8. 1 @ 28×33-in. 3-cell Denver Sub-A machine.
9. 1 @ 18×12-ft. thickener; feed 18 to 20% solids, spigot 50% solids; 1 @ 6×6-ft. drum filter, cake 25% moisture; 1 @ 4×25-ft. indirect-heat rotary drier (1 t.p.h.) to 0.1% moisture.
10. 95% talc, 90% <200-m.
11. 1 @ 8-cell 22×27-in. Denver Sub-A machine.
12. About 90% magnesite.
13. Reground in a Raymond 5-roll high-side mill to 99.9 <325-m., or in a Micronizer to <5- or 6-μ.

FIG. 92. EASTERN MAGNESIA TALC CO.

Summary. Crushed in 3 stages; dry-ground; air-classified; classifier reject conditioned, tabled, and floated one-stage.

44. TRIPOLI

Properties. The earthy siliceous products of weathering limestone or calcareous chert are often called SOFT SILICAS to distinguish them from finely ground quartz, called HARD SILICA or POTTER'S FLINT. All soft silicas other than diatomite are classed as tripoli by the U. S. Bureau of Mines, and the term TRIPOLI has often been applied erroneously even to diatomite or tripolite, deposits of which have long been known near Tripoli, in northern Africa. On the other hand, efforts have been made to restrict the term tripoli to abrasive earths produced in Missouri and Oklahoma and to call other soft

silicas, notably the Illinois-Tennessee types used mainly as fillers, AMORPHOUS SILICA. Strictly, the latter is chalcedonic quartz with cryptocrystalline structure and its average grain size (about 0.002-mm.) is smaller than that of the Missouri-Oklahoma product (<0.01-mm.). The Missouri-Oklahoma product is darker in color (mostly cream to pink) and, owing to its high porosity, has a lower apparent specific gravity; it bulks about 30 cu. ft. per short ton in place and about 45 cu. ft. when broken and stored in drying sheds. The freshly mined rock carries over 30% moisture; the fines may carry as much as 52%.

Commercial tripoli almost always contains at least 95% and often 98% or more SiO_2. Most varieties, except the hardest Illinois rock, can be cut by the fingernail, and small pieces can be rubbed to powder between the fingers. The Illinois phase is much more coherent and the Arkansas variety does not break down into individual grains though it may be water-ground readily to a soft, smooth talclike material having individual sharp-edged particles smaller even than the Illinois phase. Microscopic examination of the ground Missouri-Oklahoma product reveals very little free quartz and even the finest particles retain a fibrous, porous structure.

Uses. Firmly coherent tripoli has been cut and used successfully as building stone; the production of cut blocks in Missouri for use as filter stones for household water purification was a large business before about 1910, when municipal filtration plants in most large towns and cities rendered such purification unnecessary. In 1937, 44% of all domestic tripoli sales were for abrasive uses, 24% as filler, 6% for concrete admixture, and 26% for filter block, foundry facing, oil-well drilling mud, and some unspecified uses, including glass making, ceramics, furnace insulation, acoustic plasters, etc. The chief filler use is in paint, where the Missouri-Oklahoma product is ruled out by its color. Abrasive uses include scouring soaps and powders, metal polishes, and as mild mechanical cleanser in washing powders for fabrics and in various metal buffing compositions. Most of the tripoli exported is used in buffing compositions, as the Missouri-Oklahoma products have gained a world-wide reputation in this field. The porous, irregular-shaped grains, it is claimed, stick to buffing wheels better than any other abrasive and yet are hard enough to abrade any metal surface without causing deep scratches.

Occurrence. All soft silicas are products of weathering, although it is postulated that the Missouri-Oklahoma deposits may have been transported and laid down as a flocculent colloidal silica in essentially their present form. The Illinois and western Tennessee Valley soft silica is generally well stratified in flat-lying beds. The Tennessee-Georgia-Alabama beds usually have definite side walls (dip 45° or less) and the leading Arkansas deposit is a 20-ft. seam that may grade into unaltered chert farther away from the mountain-flank outcrop. The Missouri-Oklahoma tripoli is found within a few feet of the surface in horizontal beds averaging 10 ft. thick, although some folding and fracturing has occurred.

Production. The average production of tripoli in the United States from 1925 to 1929 was 31,782 short tons a year valued as sold (mostly ground) at $501,394. In 1937 the output was 34,936 tons realizing $450,570. Ordinarily Illinois supplies at least one-third and the Missouri-Oklahoma district more than one-half of the domestic total. Arkansas also is becoming an important source. Other producing states are California, Georgia, and Tennessee. Included in these figures, too, is a small output of finely ground Pennsylvania ROTTENSTONE, which is a more or less decomposed argillaceous limestone or black shale and not tripoli. Tripoli has been produced in France, Spain, Germany, and perhaps other countries, but no material resembling the Missouri-Oklahoma products is produced elsewhere (except perhaps in Germany) and several thousand tons a year of these products are exported.

Selling. The Missouri-Oklahoma tripoli is roughly graded into 5 sizes: (1) AIR-FLOAT, all <200- and 98% <325-m.; (2) PARTING, 98 to 99% <200-m.; (3) ADMIX, 90% <200-m. and 30% <10-μ; (4) BUFFING, all <40- and 80 to 85% <200-m.; and (5) EXTRA FINE ADMIX, 70% <10-μ. Most products are packed in paper or paper-lined jute bags and are sold direct to consumers and to dealers. No standard specifications or tests exist, although both buffing powder and fillers can be matched against samples from previous shipments, for color in water or paint vehicles, for grit by rubbing out with light oil on polished glass, and for oil adsorption and bulking qualities like paint pigments. Owing to the lack of standardization, established buying habits offer serious resistance to the marketing of products from a new source.

Crude silica sells for as little as $2 or $3 per ton, f.o.b. mines, and ground tripoli is priced all the way from $8 to $40 per ton, f.o.b. mill. Average annual sales realizations for crude and refined products have ranged recently between $13 and $17 per ton.

Treatment. Crude material as it comes from the mine generally has to be sorted or graded for color and texture and then air-dried, the Missouri-Oklahoma product being ricked in sheds for 6 mo. before going to the mill, where it is reduced by hammer mill or coal breaker and rolls to pass about 1/4-in. before going through a rotary drier. Hardinge or tube mills pulverize the dried material in closed circuit with Hum-mer or mechanical vibrating screens. All mill operations are housed so exhaust fans can remove dust to baghouses. Cyclone collectors remove intermediate products. Illinois silica is mostly treated wet, although dry grinding with air classifiers makes seven products, which grade from 65 to 99.9% <325-m.

45. VERMICULITE

Properties. The name VERMICULITE includes a considerable group of minerals that give off water and expand greatly—in commercial grades as much as 16 times in one direction—when heated. They generally have the appearance of a bronze mica, but the leaves are soft and inelastic. When expanded the color ranges from silver to golden or darker color, depending partly on the rate of heating and on the amount of oxygen present. The best qualities bulk 6 lb. or less per cu. ft. after being exfoliated, forming corklike pellets that resist abrasion. Varieties that explode or fly apart into small flakes are of little value unless or until more demand develops for sizes smaller than about 14-m.

Uses. The main use of expanded vermiculite is for insulating houses. Smaller quantities are mixed with suitable binders and made into wall board and heat- and sound-insulating blocks and cements. Miscellaneous uses include sponge rubber (mixed with latex), decorative finishes, acoustic plasters, lubricants, wall paper printing, and paint extender. Ultrafine powder (98% <325-m.) is used in aluminum paints as extender and in automobile motors and transmission to cool and lubricate. A water-floated product replaces graphite in oilless bearings. A mixture of raw and expanded vermiculite has been patented for use as motor dope to seal the rings of worn automobile engines.

Production. Vermiculite is typically an American product, mined originally and principally in Montana and to a minor extent in North Carolina, Wyoming, and Colorado. Domestic output rose to 26,556 short tons valued at $260,664 in 1937, some of which was exported to Canada and Europe. Russian material has been exploited but is not well-liked in this country. South African deposits are said to be promising.

Selling. Raw vermiculite is shipped from western mines to expanding plants in various consuming centers, most of which are either owned by or licensed under patents owned by the leading mining company. Clean unexpanded vermiculite, suitably sized for making house fill, is priced (1937–40) at $12 per short ton, f.o.b. Libby, Mont., plus freight, which ranges from a minimum of $6.60 to Minneapolis, Minn., to $16.50 to Boston, Mass., in carload lots (usually 43 tons). Expanding and bagging costs about $6, making a total cost around $30 per ton, including shrinkage. The product is marketed in bags containing 4 cu. ft. (under 24 lb.) which retail at 90¢ to $1.35 each and are sold to building-supply dealers and contractors at 70 to 82¢ each (equivalent to $56 to $68 per ton). North Carolina raw material fetches only $6 or $7 per ton f.o.b. mines, owing to large loss in fines during expansion.

Approximately 60% of consumption is for house fill which calls for material sized 3~14-m. Fastest growing use is in concrete, chiefly as 1 : 8 mix with Portland cement; this may be poured in place or pre-cast into light-weight, fireproof slabs that can be worked like lumber. ACOUSTICAL PLASTERS (3 parts gypsum to 1 part vermiculite), another growing outlet, uses either 10~20-m. or 16~24- or 30-m. material.

Several small operators, after failing to make expenses by shipping raw vermiculite to distant points, have built expanding plants, sell house fill locally, and make plaster and concrete products from fines that otherwise might be wasted.

Treatment. Raw vermiculite is prepared in cleaning plants at or near the mines by crushing, hand-picking, screening, and drying. At Libby, Mont., the yield of salable material has so increased that little more than 2 tons is mined per ton of sized raw product shipped. At this plant all >3/4-in. material is rejected and >1/2-in. (JIGGER SCREEN) is reduced in a hammer mill before joining undersize on the way to a baffled, conical-shaped, oil-fired flash drier (300° F.). The dried material is roughly sized on Hum-mer screens, and cleaned in 32 specially built air separators which yield concentrate, middling, and waste. Concentrate goes to a 5×16-ft., oil-fired rotary drier, thence to a triple-deck jigger screen, yielding four sizes designated as 1A, 1, 2, and 3 (respectively, 1/2-in.~3-m., 3~14-, 10~20-, and 16~24-m.). Middling, mainly small thick books of vermiculite, is returned to hammer mills. Elsewhere as much as 80% of the mine product may be rejected in addition to a large wastage of fines in selective mining. Fines can be froth-floated, like mica, and coarser material can be agglomerate-tabled with high efficiency; the reagents, however, should be chosen so as not to discolor the product after furnacing.

For exfoliating, some plants calcine in patented rotary furnaces, usually oil-fired; oil-fired shaft furnaces are also employed. In a typical expanding unit (*19 ACerS 94*) raw vermiculite is fed into a preheating chamber comprising a double-walled vertical cylinder. Air for gas burners is preheated by passing through the annular space between the walls, and the combustion products pass up through the inner cylinder which contains conical baffles to impede the falling vermiculite. Six burners using preheated air and city gas are placed in the primary expanding chamber (in effect, a continuation of the preheating chamber) where a temperature of 2,000° F. is maintained. The expanded material is removed from this chamber by a flight conveyor. Much of the dust is removed by an exhaust fan connected with the tops of the expanding furnace and the plant elevators. Rock and unexpanded vermiculite are removed against an air current through a slot in the bottom of the chute leading from the product elevator to the bagging line. Dust loss is 2% and rock loss 7%.

SECTION 3A

CEMENT

BY

C. H. BREERWOOD

VICE PRESIDENT AND GENERAL MANAGER, VALLEY FORGE CEMENT CO.

1. INTRODUCTION

Definitions. CEMENT is a mixture of artificial mineral-like oxide-type compounds, similar in composition and probably in structure to the natural silicates. It is made by burning together limestone and a natural carrier of SiO_2 and Al_2O_3 such as clay or shale. Fe_2O_3, added as hematite or mill scale, is normally also present. The principal cement compounds are tricalcium silicate ($3CaO \cdot SiO_2$), dicalcium silicate ($2CaO \cdot SiO_2$), tricalcium aluminate ($3CaO \cdot Al_2O_3$) and tetracalcium aluminoferrite ($4CaO \cdot Al_2O_3 \cdot Fe_2O_3$). The symbols for these four compounds are universally abbreviated in the literature of cement as C_3S, C_2S, C_3A, and C_4AF respectively. Most cements contain also small proportions of gypsum, added during the grinding; further small quantities of MgO, Na_2O and K_2O, which are almost invariably present in the raw materials; and minute amounts of one or more of the oxides TiO_2, P_2O_5, and Mn_2O_3, also introduced with the raw feed.

Table 1. Analyses and tests of 100 commercial Portland cements (*40 Pro. ASTM 988*)

Item	Range	Average
SiO_2	23.6 to 19.0	21.1
Al_2O_3	7.1 to 2.8	5.1
Fe_2O_3	6.0 to 1.8	3.0
CaO	66.3 to 61.2	63.6
MgO	5.4 to 0.7	2.4
SO_3	2.6 to 1.4	1.8
Ignition loss	4.1 to 0.6	1.5
Insoluble residue	0.45 to 0.03	0.16
TiO_2	0.64 to 0.03	0.24
P_2O_5	0.63 to 0.00	0.14
Mn_2O_3	0.69 to 0.01	0.11
Na_2O	1.20 to 0.00	0.27
K_2O	1.41 to 0.20	0.46
Free CaO	3.00 to 0.10	1.00
C_3S	62.5 to 26.8	51.0
C_2S	42.9 to 7.6	22.2
C_3A	14.1 to 0.7	8.5
C_4AF	18.2 to 5.5	9.1
<200-m	99.9 to 84.3	93.0
<325-m	97.5 to 70.0	85.7
Surface area, sq. cm. per gm. *a*	2,250 to 1,160	1,660
Tensile tests, lb. per sq. in.:		
3-day	375 to 130	289
7-day	490 to 245	360
28-day	505 to 290	409
Compression tests, lb. per sq. in.:		
7-day	5,960 to 2,810	4,667
28-day	8,730 to 3,990	5,900
1-year	9,600 to 5,600	7,512
5-year	10,030 to 5,530	8,310

a By turbidimeter.

The four principal cement compounds are all anhydrous, but have the property, essential to their use as cement, of reacting with water to form hydrates which are relatively insoluble in water and which have cementitious properties not unlike those of glue and gelatin, including the property of increase in strength as the amount of free water is decreased by progressive hydration. For discussion of the chemical reactions and physical mechanisms of setting and hardening of cements see *The chemistry of*

cement and concrete, by F. M. Léa and C. H. Desch; Longmans, Green & Co., New York (1935), and the bibliography therein cited.

Uses. Cement is primarily a structural material, used to bond together sand and/or rock aggregate and/or metals, such as steel, for such massive structures as dams, heavy retaining walls, large foundations, and the like; for slabs, as in pavements, floors, and walls; for structural members, *e.g.*, beams and columns; and for facings and protective coatings as in plasters, Gunites, etc.

Kinds of cement. The great bulk of all cements now manufactured and used is Portland cement, so named from a color resemblance of the set cement to a well-known English building stone. The usual raw materials are limestone and clay or shale, plus, usually, a small amount of ferric oxide. Characteristic properties of commercial Portland cements (ASTM, type I, see *post*) are given in Table 1. Other cements of special nature and properties are the POZZOLANAS and pozzolanic cements, blast-furnace cements, aluminous cements, masonry cements, waterproof cements, and colored cements.

Pozzolanas are highly siliceous, slightly consolidated, fine-grained rocks such as volcanic tuffs and diatomaceous earth which have the property of reacting with lime in aqueous solution to form the insoluble hydrated calcium silicates characteristic of set cements. Pozzolanic cements are mixtures of Portland cement and pozzolana, the latter being added to combine with free lime, either left in burning the Portland cement or formed by hydrolysis of C_3S during the setting reaction. Soundness is thus aided.

Slag cements. Slag obtained as a by-product from iron blast furnaces contains the same oxides that are present in Portland cement. Granulated, ground, and mixed with hydrated lime it forms COLD-PROCESS SLAG CEMENT. Granulated and ground with Portland-cement clinker it forms PORTLAND BLAST-FURNACE CEMENT. Blast-furnace slag, replacing clay and shale, is used together with suitable proportions of limestone in making ordinary Portland cement.

Aluminous cements are those in which alumina and iron largely replace silica as the acid oxide. The raw materials are limestone and ferruginous bauxite. Burning comprises fusion in blast or reverberatory furnaces. Characteristic properties are extremely rapid hardening, very high early strength, high resistance to sulphate and to mild acid waters.

Masonry cements, waterproof cements, and colored cements. MASONRY CEMENTS are mostly mixtures of Portland cement with added substances, *e.g.*, finely divided siliceous material, raw ground limestone, clay, clay and limestone, ground slag, hydrated lime, and Rosendale or natural cement. WATERPROOF CEMENTS are usually Portland cement with stearates added. COLORED CEMENTS are ordinarily white Portland cement, or gray Portland cement, with colored pigments added. Their composition and compounding are specialties.

Specifications. Cement is defined as an article of commerce by means of both chemical and physical properties and limits. The common property sought in all cements is the

Table 2. Chemical requirements for cements (*After ASTM C-150-41*)

	Type I	Type II	Type III	Type IV *a*	Type V *a*
Silicon dioxide (SiO_2), min., %	....	21.0	....	....	24.0

a See note, Sec. 1 of the full specification.

b Expressing chemical limitations by means of calculated assumed compounds does not necessarily mean that the oxides are actually or entirely present as such compounds. The percentages of tricalcium silicate, dicalcium silicate, and tricalcium aluminate shall be calculated from the chemical analysis as follows:

Tricalcium silicate =

$$(4.07 \times \% \text{ CaO}) - (7.60 \times \% \text{ SiO}_2)$$

$$- (6.72 \times \% \text{ Al}_2\text{O}_3) - (1.43 \times \% \text{ Fe}_2\text{O}_3) - (2.85 \times \% \text{ SO}_3).$$

Dicalcium silicate =

$$(2.87 \times \% \text{ SiO}_2) - (0.754 \times \% \text{ 3CaO}\cdot\text{SiO}_2).$$

Tricalcium aluminate =

$$(2.65 \times \% \text{ Al}_2\text{O}_3) - (1.69 \times \% \text{ Fe}_2\text{O}_3).$$

Oxide determinations calculated to the nearest 0.1% shall be used in the calculations. Compound percentages shall be calculated to the nearest 0.1% and reported to the nearest 1%.

capacity to cement together the chemically inert but structurally strong fillers, sand, rock, and steel. This property is measured by the tensile and compressive strengths of test blocks of neat cement and/or of cement-sand plasters, made under closely specified standard conditions of proportioning, mixing, casting, storage, and subjection to the test forces. Other special properties required by the user for particular services are high or low speed of setting, early development of strength, low heat evolution during setting, and exceptional resistance to attack and disintegration by fluids, particularly natural waters containing relatively high concentrations of dissolved acids and salts. These properties are in part determined by direct physical tests and in part by established correlations with other physical properties, *e.g.*, fineness; with chemical analyses, and with compound compositions (Art. 3).

Standard American specifications for Portland cement have been issued by the American Society for Testing Materials (*ASTM C-150-41*). They contemplate and describe five types, as follows:

Type I: For use in general concrete construction when the special properties of the other types are not required.

Type II: For general concrete construction exposed to moderate sulphate action, or where moderate heat of hydration is required.

Type III: For high early strength.

Type IV: For low heat of hydration.

Type V: For high sulphate resistance. Designed principally for salt-water work.

Chemical limits for the different types are given in Table 2 and physical requirements in Table 3.

Table 3. Physical requirements for cements (*After ASTM C-150-41*)

	Type I	Type II	Type III	Type IV *a*	Type V *a*
Fineness, specific surface, sq. cm. per gm.					
Average value, minimum	1,600	1,700	....	1,800	1,800
Minimum value, any one sample	1,500	1,600	....	1,700	1,700
Soundness:					
Autoclave expansion, max., %	0.50	0.50	0.50	0.50	0.50
Time of setting (alternate methods): *b*					
Gillmore test:					
Initial set, min., not less than	60	60	60	60	60
Final set, hr., not more than	10	10	10	10	10
Vicat test:					
Initial set, min., not less than	45	45	45	45	45
Final set, hr., not more than	10	10	10	10	10
Tensile strength, lb. per sq. in.: *c*					
The average tensile strength of not less than three standard mortar briquets, prepared in accordance with Methods C 77, shall be equal to or higher than the values specified for the ages indicated below:					
1 day in moist air	....	....	275	....	....
1 day in moist air, 2 days in water	150	125	375	....	....
1 day in moist air, 6 days in water	275	250	....	175	175
1 day in moist air, 27 days in water	350	325	*c*	300	300
Compressive strength, lb. per sq. in.: *c*					
The average compressive strength of not less than three mortar cubes, prepared in accordance with Method C 109, shall be equal to or higher than the values specified for the ages indicated below:					
1 day in moist air	....	....	1,300	....	....
1 day in moist air, 2 days in water	1,000	750	3,000	....	....
1 day in moist air, 6 days in water	2,000	1,500	....	800	1,000
1 day in moist air, 27 days in water	3,000	3,000	*c*	2,000	2,200

a See Note, Sec. 1 of the full specification.

b The purchaser should specify the type of setting-time test required. In case he does not so specify, the requirement of the Gillmore test only shall govern.

c The purchaser should specify the type of strength test required. In case he does not so specify, the requirements of the tensile strength test only shall govern. The strength at any age shall be higher than the strength at the next preceding age. Tests at 28 days on Types I and II cement may be waived at the option of the purchaser. If, at the option of the purchaser, a 28-day test is required on Type III cement, the strength at 28 days shall be higher than at 3 days.

Chemical specifications for Type I simply limit the objectionable ingredients, but the physical requirements serve to impose reasonable limits on the principal ingredients as well.

Most commercial Portland cement is furnished under this specification. Comparison with Table 1 shows that the specified chemical maxima are rarely exceeded, whereas the averages of the strength tests are well in excess.

Special properties are obtained by enhancement or suppression of one or another of the cement compounds in the clinker. Thus for HIGH EARLY STRENGTH the C_3S/C_2S ratio is increased, owing to the capacity of C_3S to hydrate and set rapidly and to develop thereupon almost full ultimate strength. C_2S, on the other hand, is very slow to set, but it develops even greater strength than C_3S at about 2 years. The contributions of the aluminous compounds to both early and ultimate strengths are substantially negligible.

Heats of hydration of the clinker compounds, as given by Bogue and Lerch (*Paper 26, Portland Cement Assoc. Fellowship, USBS*), are: C_3A, 207 cal. per gm.; C_3S, 120; C_4AF, 100; C_2S, 62. Hence in specifying and making cements for use in massive concrete structures, where temperature of upward of 50° C. above final temperature may develop owing to hydration, and shrinkage cracks and consequent weakness result on cooling, the silica modulus (p. 09) is made high and the lime modulus low, which increases production of C_2S instead of C_3S.

Resistance to sulphate waters increases with decrease in C_3A content (*40 ASTM 988*).

Shrinkage after setting is most pronounced with high C_3A; C_3S appears to shrink least; C_2S is intermediate (*38 #2 ASTM 419*).

Fineness of cement has great effect both on early strength and heat evolution during setting, owing to the fact that it accelerates the hydration reaction. It is, therefore, desirable in cements for rapid hardening and high early strength; undesirable for the low-heat varieties.

Special specifications are frequently drawn by large buyers in the attempt either to obtain a cement particularly suited to their use, or for commercial reasons. U. S. GOVERNMENT SPECIFICATIONS, which preceded the A.S.T.M. specifications, covered the same general types of cement, and were largely adopted by A.S.T.M. in setting up the standard American specifications given in Tables 2 and 3. NEW YORK CITY BOARD OF WATER SUPPLY SPECIFICATIONS enforce rigid limits as to chemical ingredients, cement compounds, free and total alkalies, and the degree of burn; they are designed principally to insure sound cement with long life and high resistance to aggressive waters. MISCELLANEOUS SPECIFICATIONS cover standard weights of ground cement; methods for testing; methods for sampling and storing; limits on objectionable ingredients; limits on adulterants; tolerances for chemical requirements; and tolerances for physical requirements.

Production of cement in U. S., by states, is given in Table 4. World production is reported in Table 5.

h Total includes estimate for other countries not mentioned.

Selling. Average selling price per barrel in bulk, f.o.b. factory, for U. S. production is given in Table 6. Cement is a bulk product, raw material for which is available in all parts of the world; hence important outlets cannot be maintained for any time against an adverse freight differential. The 157 plants in the U. S. are well scattered over 36 states; any marked stable increase in demand from one or all of the other 12 states can be expected to be answered by a new plant therein.

Footnotes have same meaning as in Table 4.

Raw materials for all cements are lime-, alumina-, and silica-bearing materials. The lime-bearing material in 90% of all cement manufacture is limestone; others are blast-furnace slags, marl, and $CaCO_3$ sludge from alkali plants. The usual aluminous materials are clay, shale, and mica. Silica is introduced in the clay and shale and further additions, if necessary, are made in the form of quartz. Iron oxide, in the form of hematite, magnetite, limonite, or mill scale, is a minor component of some cements. Gypsum may be added to the clinker during grinding (Art. 5) to control setting qualities. Rarely calcareous shales or deposits of interbedded limestone and shale are of suitable composition for standard raw-material mixes as mined. In most cases more or less adjustment of chemical composition is necessary prior to burning for each and all of the cements made by any given plant (see Arts. 2 and 7).

Materials used to manufacture cement in U. S. plants and the numbers of plants using each material are: limestone and clay, 72; limestone and shale, 33; limestone, shale, and clay, 5; limestone, shale, and sandstone, 2; limestone, marl, and clay, 3; marl and clay, 5; argillaceous limestone and high-grade limestone, 12; blast-furnace slag and limestone, 8; argillaceous limestone, 9; shells and clay, 4; chalk and clay, 1; argillaceous limestone, shale, and clay, 1; waste lime from alkali plants with clay, 2.

MANUFACTURE

Successive steps in the manufacture of cement are: mining the raw materials, preparation of raw materials, heat treatment, grinding clinker, and handling the finished product.

Mining. The cement rocks—limestone and clay or shale—are relatively soft and shallow-lying. Mining is done in the great majority of cases by quarrying. Normally this involves removal of an overburden of soil and organic material, and some underlying dirty clay or disintegrated shale. The rock itself is then drilled and blasted. For discussion of standard methods see *Peele*. Cost of stripping, mining, and delivery to the primary crusher in well-organized quarries does not, in general, exceed 20¢ per short ton of raw rock (1942); costs much lower than this have been attained with favorable quarrying conditions.

2. PREPARATION OF RAW MATERIAL

Preparation consists in comminution and in adjustment of chemical composition. The sequence of operating steps depends upon whether the process is wet or dry. Wet-process plants, *i.e.*, those in which raw-material grinding and the adjustment of composition are done wet, and the thick wet pulp (slurry) is fed to the kiln, comprised 93 out of 157 plants operating in the United States in 1942; the wet process is used for 94% of the new capacity provided here since 1927. In DRY-PROCESS PLANTS the crushed rock is dried, the components are mixed, ground, stored, blended to adjust composition, and sent dry to the kiln.

Table 7. Costs of primary crushing (per long ton)

Item	Costs, $ per ton	
	100- to 150-ton plants	300-ton plants
Operating labor	0.0274	0.0092
Operating supplies	0.0024	0.0016
Maintenance labor	0.0055	0.0031
Maintenance material	0.0058	0.0048
Power	0.0060	0.0057
Total	0.0471	0.0244

Crushing

Crushing reduces run-of-quarry materials to a size (usually <3/4-in.) suitable for feed to the pulverizers. The reduction may be two- or three-stage. Jaw or gyratory crushers (Sec. 4, Arts. 2 and 3) are the usual primary machines, but single-roll crushers (Sec. 4, Art. 5) are often used where character of rock permits. Hammer mills (Sec. 4, Art. 9), cone crushers (Sec. 4, Art. 7), and rolls (Sec. 4, Art. 8) are used as secondary crushers.

Costs. The controlling factors in crushing costs are the size and character of the quarry rock, its moisture content and the tendency of moisture to produce stickiness, the design of the plant, and the efficiency of operation.

Cost of primary crushing (1942) for stone of average hardness from power-shovel size to about 6-in., ranged from about 4.5¢ per long ton at plants of average size (100 to 150 t.p.h.) to about 2.5¢ at larger plants (300 t.p.h.). These costs include conveying to the raw-grinding department; they do not include plant overhead, interest, depreciation, taxes, etc. Typical breakdowns are shown in Table 7.

Table 8. Costs of secondary crushing (per long ton)

Item	Costs, $ per ton	
	100- to 150-ton plants	300-ton plants
Operating labor	0.0136	0.0042
Operating supplies	0.0015	0.0006
Maintenance labor	0.0064	0.0040
Maintenance material	0.0079	0.0067
Power	0.0176	0.0103
Total	0.0470	0.0258

Costs of secondary crushing (6- or 8-in. to <3/4-in.) range from 4.7¢ per long ton for average-size plants to 2.6¢ per ton for larger plants. Typical breakdowns are given in Table 8.

Drying

Drying before grinding is necessary in dry-process plants to insure effective operation of the grinding mills. Direct-heat rotary driers (Sec. 17, Art. 3) fired with pulverized coal or by grate stokers are usual, but waste heat from the kilns is sometimes used. Customary

practice is to dry between the secondary crushers and storage, but in several recent plants drying is done in the grinding system by circulating hot gases (700° F.) from special oil-fired furnaces through the system and thence through bag-type dust collectors, using a suction fan beyond the dust collectors to remove the moisture-laden gases at about 150° F.

Table 9. Costs of drying (per short ton)

Item	Limestone and shale	Argillaceous limestone
Operating labor	$0.046	$0.018
Operating supplies	0.002	0.0003
Maintenance labor	0.010	0.005
Maintenance material	0.013	0.003
Coal (5 lb. at 1/4¢)	0.040	0.005
Power	0.011	0.024
Total	$0.122	$0.055

Costs. In drying argillaceous limestone, when moisture does not average much above 3%, costs of 6¢ per short ton can be attained with modern pulverized-coal-fired driers. In several hot-air grinding installations limestone is dried for less than this. Where limestone and hard shale are the raw materials, and the shale carries much moisture, costs run as high as 12¢ per ton. Cost breakdowns are given in Table 9.

Crushed-rock storage

Storage for crushed basic raw materials (limestone, shale, clay, silica, iron, diaspore, coal, and gypsum) and for clinker and the handling of the materials therethrough are important parts of cement-making procedure. Standard practice, almost universally adopted, is to use a compartmented bin, ordinarily several hundred feet long, 60 to 100 ft. wide, covered, with overhead cranes and grab buckets under the cover for stocking and recovering the materials of large bulk. Fig. 1 illustrates the recent installation at the

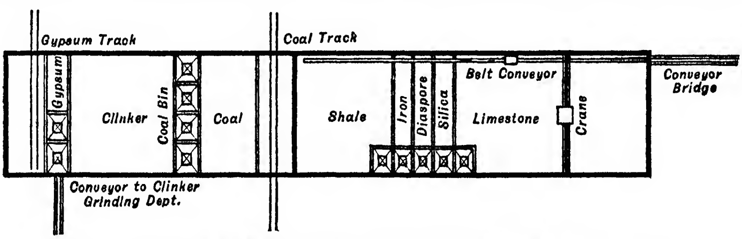

FIG. 1. Material storage at Hawkeye plant, MARQUETTE CEMENT MFG. CO.

Hawkeye plant of MARQUETTE CEMENT MFG. CO. It is 467 ft. long, 80 ft. wide, under a roof 60 ft. high, served by a 75-ft. crane with 3-cyd. grab bucket. The raw and in-process materials are delivered by belt conveyor and by cars above the wall level and are dumped in a pile into their respective receiving or bulk-storage compartments. They are then distributed as necessary by the crane, either to other parts of bulk storage or into the conveyor-feed bins. These conveyor-bins are usually provided with constant-rate feeders to permit proper proportioning onto the convéyors to the grinding mills. Coal is similarly handled.

Table 10. Cost of storage and handling at wet-process plants (per bbl. of cement) *a*

Item	Average-size plants	Large plants
Operating labor	$0.0083	$0.00498
Operating supplies	0.0001	0.00010
Repair labor	0.0035	0.00230
Repair material	0.0020	0.00180
Power	0.0019	0.00163
Total	$0.016	$0.011

a Includes stone, clinker, sand, and iron, stocked and placed in bins.

Open storage, with recovery by overhead or crawler cranes with grab buckets, is used at a few plants. COAL and CLINKER are sometimes stored in covered concrete silos. This practice makes for cleanliness and ease of handling, and answers occasional rigid specifications which require that no moisture come in contact with clinker.

Cost per barrel of cement for storing and handling crushed basic raw materials ranges from 1.1¢ for large plants to 1.6¢ for average-size plants. 1.5¢ is a fair average. See Table 10.

Proportioning *

Proportioning is the first step (blending and burning being subsequent steps) in the chemical control necessary to produce specification cements. It comprises mixing the feed to the raw pulverizers (MAKING THE MIX) in quantities predetermined by calculations

* By M. D. Olver, Vally Forge Cement Co.

which take into account the analyses of the raw materials, the combining ratios in the kiln, and the chemical specifications for the finished cement.

Proportioning starts with the deposits of limestone rock, and of clay and/or shale. Knowledge as to the composition of these in place, ahead of the mining, should be kept up to date by sampling of blast holes. When the deposits are fairly uniform, the raw materials can be held close to an average composition by thin-bedding in storage by means of a traveling tripper on the crushed-rock storage conveyor. If the deposits are variable the high-, low-, and medium-lime rocks should be stored separately after crushing and thereafter be drawn proportionately (as by number of crane buckets) in recovery.

Quartz, hematite, and diaspore are stored separately for correction of SiO_2, Fe_2O_3, and Al_2O_3 respectively. Their analyses are determined as brought in, before unloading and storage.

Calculation of mix is based on one or another of a number of empirical formulas designed, in connection with the conditions of burning, to produce the desired compound composition. The original LE CHATELIER FORMULA (1882) was $(CaO + MgO)/(SiO_2 + Al_2O_3) = 3$, the quantities of the various oxides being taken in mols. This formula was based on the assumption that the ratio of basic to acid oxides in cement is 3, that MgO is equivalent to CaO, and that Fe_2O_3 requirements for lime could be neglected. The NEWBERRY FORMULAS, $CaO = 2.8SiO_2 + 1.1Al_2O_3$, and $CaO = 2.5SiO_2 + 1.6Al_2O_3$, in which the quantities are weight percentages, were used for many years. The first was based on the assumption that the cement compounds were C_3S and C_2A, that MgO did not replace CaO, and that Fe_2O_3 might be ignored; the second varied these assumptions in accord with the finding (*39 # 4 AJS 1*) that the aluminate is C_3A, and decreased the silica coefficient to allow for imperfect incorporation due to inadequate raw grinding and mixing. Eckel (*Cements, limes and plasters;* 1928) proposed the formula $CaO + 1.4MgO = 2.8SiO_2 + 1.1Al_2O_3 + 0.7Fe_2O_3$, returning to Le Chatelier's assumption that MgO can act as a base in cement formation and including Fe_2O_3 among the acidic constituents. For a cement with maximum lime content, the clinker compounds are C_3S, C_3A, and C_4AF. The mix formula for such a cement, based on percentage weights, is $CaO = 2.8SiO_2 + 1.65Al_2O_3 + 0.35Fe_2O_3$. Practice shows that with such high lime contents in the kiln feed, free lime is present in equilibrium with the liquefied compounds at clinkering temperatures and that the highest practicable lime content in the mix to produce a cement without free lime is given by the formula $CaO = 2.90SiO_2 + 1.18Al_2O_3 + 0.65Fe_2O_3$. Even this lime modulus (Kühl, *18 Z 833*) cannot be maintained without fine raw grinding, adequate mixing, and time-temperature conditions in the kiln that insure complete combination.

Moduli. SILICA MODULUS is defined as $SiO_2/(Al_2O_3 + Fe_2O_3)$. IRON MODULUS = Al_2O_3/Fe_2O_3. In both cases weights or percentage weights are used. HYDRAULIC MODULUS equals $CaO/(SiO_2 + Al_2O_3 + Fe_2O_3)$ where the numerical values are expressed in mols. Values of silica and iron moduli and usual lime equations for the various A.S.T.M. type cements are given in Table 11.

Table 11. Moduli for proportioning mixes for type cements

Type of cement	Iron modulus	Silica modulus	Lime equation *a*
Standard	2.30	2.36	2.10
Moderate-heat	1.32	2.64	2.10
High-early	2.30	2.30	2.30
Low-heat	1.00	3.32	1.94
Sulphate-resistant	1.05	3.62	1.99

a $CaO/(SiO_2 + Al_2O_3 + Fe_2O_3)$.

Calculation of raw mix for a cement with a prescribed lime modulus (*e.g.*, 2.10) from given raw materials follows: RAW MATERIAL analyses are given in Table 12, Cols. 1, 2, 3. STOICHIOMETRY: Base =

Table 12. Results of calculations for a cement with a given (2.1) lime ratio

Loss *a*	34.1	43.2	21.0	36.1	....	0.8	0.8	0.8
Weight, %	100.0	100.0	100.0	100.0	100.0	4.0	104.0	100.0

a CO_2 and/or H_2O.
b Based on weight of clinker.
c Equals 104% of finished cement.
d Lime ratio = 65.4/(21.5 + 7.0 + 2.7) = 2.09
e Lime ratio = 64.1/(20.7 + 6.7 + 2.6) = 2.13

100 lb. cement rock. Let y = weight of limestone to be added. Write equations, from Cols. 1 and 2, for the weights of the four oxides in the mix, thus:

$$\begin{aligned}\text{Total } SiO_2 &= 0.172 \times 100 + 0.01y\\ \text{" } Al_2O_3 &= 0.056 \times 100 + 0.005y\\ \text{" } Fe_2O_3 &= 0.02 \times 100 + 0.005y\\ \text{" } CaO &= 0.386 \times 100 + 0.538y\end{aligned}$$

Substitute these quantities in the lime-ratio equation (note *a*, Table 11):

$$(38.6 + 0.538y)/(24.8 + 0.02y) = 2.1$$

whence y = 27.2 lb. limestone to be added per 100 lb. of cement rock, or the raw mix is 78.6% cement rock and 21.4% limestone, with the analysis shown in Col. 4. The sum of the nonvolatile oxides in the raw mix (which persist through burning) is 63.9%. Hence the composition of clinker will be the sum of the quotients obtained by dividing the percentages of these nonvolatile oxides in Col. 4 by 0.639 (see Col. 5). When this clinker is ground, 4% of gypsum, based on the clinker, is to be added (Col. 6 = 0.04 × Col. 3), yielding 104 lb. per 100 lb. of clinker (Col. 7), whence the finished cement (Col. 8) is calculated by dividing by 1.04.

Calculating mix from two moduli. Components analyze as follows:

	SiO_2	R_2O_3	CaO	MgO
Limestone......	2.0	1.0	54.4	0.8
Shale...........	53.0	24.4	7.4	0.1
Sand...........	92.1	5.0	1.6	0.5

Given moduli are: Silica, 2.4; lime, 2.0.

Let y = lb. shale in mix, z = lb. sand, 100 = lb. limestone. Then, per 100 lb. of limestone,

$$SiO_2 \text{ in mix is: } 0.02 \times 100 + 0.53y + 0.921z$$

$$R_2O_3 \text{ in mix is: } 0.01 \times 100 + 0.244y + 0.050z$$

$$CaO \text{ in mix is: } 0.544 \times 100 + 0.074y + 0.016z$$

SILICA-MODULUS EQUATION is: $2.4 = \dfrac{2 + 0.53y + 0.921z}{1 + 0.244y + 0.05z}$

LIME-MODULUS EQUATION is: $2.0 = \dfrac{54.4 + 0.074y + 0.016z}{2 + 0.53y + 0.921z + 1.0 + 0.244y + 0.05z}$

Solving these equations simultaneously, y = 29.53 lb.; z = 2.55 lb. Analysis of mix is then computed as in Table 12*a*.

Table 12*a*. Calculations for cement with two moduli set

Item	Lb.	SiO_2	R_2O_3	CaO	MgO
Limestone......	100	2.0	1.0	54.4	0.8
Shale..........	29.5	15.64	7.20	2.18	0.03
Sand...........	2.5	2.30	0.12	0.04	0.01
Totals........	132.0	19.94	8.32	56.62	0.84
Kiln mix *a*......	64.9	15.1	6.3	42.9	0.6
Clinker *b*.......	100.0	23.3	9.7	66.1	0.9

a Oxide weights are 100/132 times those in preceding line.
b Preceding line changed to 100-lb. basis.

Check:

$$SiO_2/R_2O_3 = 23.3/9.7 = 2.4$$

$$CaO/(SiO_2 + R_2O_3) = 66.1/(23.3 + 9.7) = 2.0.$$

Regulation of quantities of the components of a mix is effected by some form of constant-weight or proportioning feeders (Sec. 18, Art. 23). In wet grinding, the clay is fed as a SLIP (aqueous pulp); Ferris-wheel feeders or orifices on constant-head tanks with agitators are used.

Grinding raw materials

The purpose in grinding the raw materials is to insure completion of the desired reactions in the kiln without being forced to employ excessive temperatures. The BURNABILITY of the charge, *i.e.*, the ease of effecting the thermal reaction, is decreased by >60-μ material, particularly quartz and mica, and is not increased by size reduction below 20-μ. Hence 60-μ should be the limiting size usually sought.

For general discussion of grinding and grinding performances see Secs. 5 and 6.

Best modern cement practice is to grind in closed circuit with wet or dry sand-slime separators, but many plants are still operating with long multi-compartment mills without size guards.

Over the period 1927 to 1942 the earlier plants, *e.g.*, VALLEY FORGE, KEYSTONE, WACO, and NATIONAL, used 3- and 4-compartment mills, about 7×36- to 42-ft., all in open circuit, three of them wet.

The recent wet plants have all been two-stage, with short ball mills in closed-circuit with rake classifiers in the primary stage; the secondary stage in two was a short ball mill in closed-circuit with a bowl classifier, whereas the other three used open-circuit tube mills. Some recent dry plants have installed ball-bearing-type mills (*e.g.*, Babcock & Wilcox) in closed-circuit with air classifiers. Other dry plants, in modernizing the raw grinding departments, have used ball mills, or the suspended horizontal-roll type mills (Bradley Hercules) for preliminary grinding, and tube mills with air separators for secondary grinding.

Table 13. Costs of raw grinding (¢ per bbl. of cement)

Item	Large plants	Average-size plant
Operating labor	$0.0060	$0.0102
Operating supplies	0.0008	0.0009
Maintenance labor	0.0034	0.0079
Maintenance material	0.0185	0.0323
Power at 5 mills per kw-hr	0.0275	....
Power at 6.75 mills per kw-hr	....	0.0381
Total *a*	$0.0562	$0.0894

a Costs include filling feed boxes over grinding machines and conveying finished material to storage tanks; they do not cover mill overhead, interest, depreciation, taxes, etc.

Raw-grinding costs (1942) for medium-size wet plants using three-compartment mills, open-circuit, with <3/4-in. feed, grinding to about 92% <200-m., average from 9 to 10¢ per bbl. of cement (29 to 32¢ per short ton of rock). At large wet and dry plants, using modern closed-circuit grinding methods, grinding through the same range costs from 5.6 to 7¢ per bbl. of cement (equivalent to about 620 lb. of rock) or from 18 to 22.5¢ per short ton. See Table 13.

Blending

Wet blending. Only under exceptional circumstances is the proportioning done in regulation of the feed to the raw-mix grinding mills sufficiently accurate to constitute the final control on the feed to the kilns. Usual modern procedure is to provide storage for the ground raw mix; for separate supplies of high-silica and high-iron materials, and to keep additional separate supplies of high- and low-lime material on hand for any necessary raw-mix corrections. Suitable handling equipment draws raw mix and corrective material from the respective supply tanks and transfers to blending and mixing tanks from which, in turn, the corrected mix is transferred to the kiln feeders.

In wet-process plants it is both possible and practicable to control the lime-silica ratio by means of centrifugal classification (Sec. 8, Art. 13) or by flotation of the raw mix. When alumina is present in the form of mica, some adjustment of alumina content is also possible by rejection of mica; this makes for soundness in the cement by lowering the C_3A and eliminating this relatively coarse ingredient from the kiln feed. Graphitic material may also be eliminated by flotation. See Sec. 12, Arts. 52, 53, 54.

In general any present-day cement is obtainable by variation of composition of raw mix through the following relatively small ranges of the various oxides: SiO_2, 6%; Fe_2O_3, 4.5%; Al_2O_3, 4%; CaO, 8%; MgO, max. content, 4%. By these variations C_3S is varied from 20 to 70%; C_2S from 0 to 60%, C_3A from 2 to 18%, and C_4AF from 3 to 18% (*148 A 374*).

Flotation of cement raw mix normally involves the following steps: (*a*) Classification by the use of hydro-bowls and centrifuges to concentrate the minerals to be retained or discarded. Hydro-bowls are used when separation at 325-m. or larger is adequate; centrifuges when separation at smaller sizes is desired. (*b*) Froth flotation of the coarse or fine calcareous material to make a relatively rough separation from the gangue minerals, usually quartz or mica, or both. COLLECTING AGENTS used are oleic acid, fish-oil fatty acid, or saponified or soap-stabilized tall oil, added in minute quantities in stages, with alcohol or resin-type FROTHING AGENTS. If graphitic material is present in sufficient amount to harm flotation of the calcitic minerals, it is either DISPERSED by the use of goulac or similar compounds; or removed first by flotation with a light fuel oil or kerosene as collector, and an alcohol frother.

What is done in any particular case by the combination of classification and froth flotation depends upon the size distribution of the minerals in the ground raw mix, and the blend that is desired for burning. The basic aims are: (*a*) to produce a float of the desired lime-silica ratio, or one that is on the high-lime side, which can be corrected by blending back a portion of fine low-lime material; (*b*) to remove mica and coarse quartz as completely as possible, because both either burn incompletely or prolong burning time unduly; (*c*) to separate fine quartz and mica, in order to obtain the fine quartz for blending back.

Example. In treating Lehigh Valley (Pa.) argillaceous limestone, it is desired to raise the lime, lower the alumina, and retain the quartz. The quartz concentrates in a >30-μ fraction, and the mica concentrates in the <30-μ fraction. Hence the ground rock is centrifuged to separate at 30-μ. The fine fraction is first floated to remove the carbonaceous material, and again floated to leave a micaceous

tailing, which is discarded. This raises the lime and lowers the alumina. The >30-μ fraction, containing the bulk of the quartz, is, of course, not processed.

If the quartz and mica are of about the same particle size, and it is desired to retain quartz and discard mica, it is usual to float the calcareous material, leaving both quartz and mica together in the tailing, then to float the mica from the quartz, using a cationic collector of medium molecular weight, *e.g.* laurylamine. The quartz is then blended back, and the mica is dried and sold.

Other methods of blending raw materials are used by wet plants, particularly when the materials do not need to be processed to produce blending stocks.

At Universal Atlas Cement Co., Leeds, Ala., the raw materials are limestone, shale, and sandstone. These are accurately proportioned from separate bins by weighing belts, ground in two stages in short ball mills in closed-circuit with classifiers, then dewatered in two @ 200-ft. thickeners in series. The variation from the holding point (percentage of CaO in raw mix) is extremely low and the slurry is dewatered to a point as low as it can be pumped and handled. At Hawkeye Portland Cement Co., Des Moines, Iowa, the raw materials, limestone, shale, silica, iron, and diaspore, are stored in separate bins and accurately proportioned by weighing feeders. This raw mix is ground in open-circuit and run to agitated slurry tanks where chemical correction can be made, if necessary; usually it is unnecessary.

Blending calculations are based on simple stoichiometry which starts from the chemical specifications for the finished cement. The gypsum and/or other subsidiary ingredients added in clinker grinding (Art. 5)— and the ash from the fuel, if powdered solid fuel is used—are deducted from this analysis to obtain the burned residue from the blend to the kiln. This is then adjusted to kiln-feed analysis on the assumption that all of the CaO and MgO in the residue came from $CaCO_3$ and $MgCO_3$, and that combined water in the clay or other alumina-bearing material is negligible. The proportions of the raw mixtures available which are necessary to produce kiln feed of the desired composition are then calculated from the analyses of these mixtures.

Example. To produce A.S.T.M. Type I (Federal 191-B) from ground products having the compositions shown in Table 14.

Table 14. Analyses used in calculation of a blended slurry to kiln

a And/or undetermined.

Solution: The SO_3 content of the *cement* corresponds to 1.8/0.465 = 3.9% of gypsum (mol. wt. $CaSO_4 \cdot 2H_2O$ = 172; SO_3 = 0.465). Hence *clinker + ash* is 96.1% of the *cement* and the analysis comprises the corresponding quantities of the *cement* analyses divided by the factor 0.96. Average *ash* from the fuel used analyzes as shown; the percentage in *clinker + ash*, based on average fuel consumption at the plant, is 1.2%. Deducting the weights of the various ingredients of this 1.2 lb. of ash per 100 lb. of clinker and ash from the *clinker + ash* leaves the respective weights in 98.8 lb. of clinker, and this, recalculated to a percentage basis, is shown as *clinker*. When this clinker was burned the loss was CO_2 in the proportions of 44 parts per 56 parts CaO, and 44 parts per 40.3 parts MgO, a total of 56.7 lb. CO_2 per 100 lb. of *clinker*. Experience with the blending stocks has shown that kiln feed made from them contains about 1.3% material undetermined by the standard analyses. Hence 100 lb. of *clinker* plus 56.7 lb. CO_2 equals 98.7% of kiln feed, whence *kiln feed* to produce the desired finished cement should have the analysis shown in Table 14. Available for blending are *raw rock*, and *processed rock* obtained by classification and flotation. The quantities of each to be taken are determined by a weight balance on CaO; thus if x is the weight of processed rock to be taken, $0.453x + 0.394(1 - x) = 0.413$, from which $x = 0.32$ or 32%, and the weight of raw rock necessary is 68%.

Wet-blending plant consists of a number of tanks of suitable capacity, with provision for agitation, and the necessary pumps and piping for transfer from tank to tank.

Layout for Valley Forge Cement Co. is shown in Fig. 2 (burning capacity, 2.43 bbl. clinker per min.). Tanks are steel, 20×23 1/2-ft. inside, with flat concrete bottoms, fitted with Dorr agitating mechanisms making 2 r.p.m. Tanks are normally filled to a depth of 21 ft. and are drawn down 20 ft. in emptying. Usual slurry is 64.5% solids. The tanks are filled from the grinding plant by 3-in. Wilfley pumps working against a pumping head (est.) of 90 ft., driven by 40-hp. motors, and delivering

through 5-in. pipe at the rate of 123 g.p.m. (0.5 gross ton solid). Circulating pumps are 4-in. Wilfleys driven by 40-hp. motors and delivering through 6-in. pipe. With two kilns burning, the plant handles 2.02 long tons of solid per min. (503 g.p.m.) with a consumption of 41 hp.

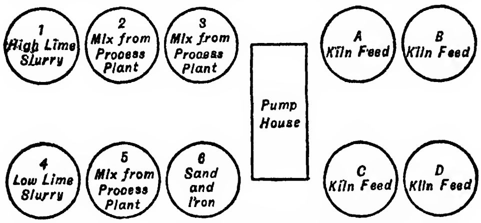

FIG. 2. Blending tanks at VALLEY FORGE CEMENT Co.

Operation involves filling a stock tank (numbered) with slurry, sampling and analyzing, and then pumping the proper quantities from two or more stock tanks to a kiln-feed tank (lettered), where, after thorough agitation, the charge is sampled and analyzed. If correction is necessary it is made by transfer of a suitable quantity of the necessary material from a stock tank. The charge is again mixed and resampled. If composition is correct, the tank is released for kiln charging; otherwise it is further corrected until the desired composition is attained.

Costs of wet-process blending and storage (operating only, 1942) are about 3.2¢ per bbl. (10.2¢ per short ton) for average-size plants and 2.1¢ per bbl. (6.7¢ per short ton) for larger plants. Breakdown is given in Table 15.

Correcting unsuitable rock. Few cement-rock deposits are of suitable composition and uniformity for day-in-and-day-out production of a high-grade cement of any type, and none will produce raw mixes for a variety of types without correction. Recent cement-buying practice is to specify composition much more closely than is indicated in Table 2, and to multiply types in the attempt to tailor the cement to the use. As a result, correction through blending is a necessity at substantially all plants. Old practice was to bring in silica, mill scale (for iron), and—unless an exceptionally high-lime rock could be quarried selectively on the property—limestone, and to blend these in as required. This is still necessary in dry-process plants. In wet-process plants, however, it is always possible, by rejecting a selected part of the mineral constituents, to produce blending stocks with which to meet all requirements of the special types, except those for high iron. Whether correction by addition or correction by rejection will be more economical in a given case depends upon the specification, the bulk of the rejection, the prices of addition materials, and the cost of the rejected material (which includes value in deposit, mining, crushing and grinding, and separating the reject).

Table 15. Costs of wet-process blending *a*

Item	Average plants	Large plants

Total	$0.032	$0.021

a Includes pumping to kiln feeders, and mechanical or air agitation; average moisture, 34 to 35%.

Comparison of the quantities involved by the two methods, when employed for the production of a given cement from a given rock, is shown in Tables 16, 17, 18. The addition method would involve supplying 54 t.p.d. of sand, 10 t.p.d. of iron scale, and 304 t.p.d. of limestone (see Table 16). The flowsheet for correction by rejection is shown in Fig. 3. Quantities and analyses are shown in Table 17. The method involves supplying 54 t.p.d. of sand and 6 t.p.d. of iron scale, and rejecting 110 t.p.d. of material which, in a cost comparison, must be charged off as cement rock, and charged with its proportion, on a tonnage basis, of the costs of mining, crushing and grinding, and the entire cost of separation. Analyses of the cements producible from the two feeds, with proper allowances for coal ash and gypsum, are given in Table 18.

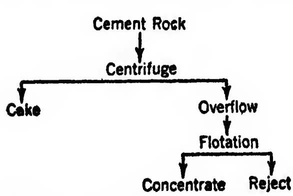

FIG. 3. Generalized flowsheet for grading-up cement rock.

Agitators. Maintenance of uniform size distribution (and, concomitantly, uniformity in chemical composition) throughout thick slurries in storage for kiln feed is not a simple problem, and it becomes more difficult the larger the limiting size of solid and the greater the storage capacity provided. In general, the deeper the tank for a given volume the easier it is to maintain uniformity therein. The usual arrangement is a combination of slow rotary agitation and bottom-introduced air, which may be injected from a plurality of jets, fixed or moving, or may be combined with air-lift piping. In large shallow tanks it is usual, also, to circulate pulp by pumps, taking suction at points on the bottom where coarse material tends to segregate, and returning over areas where there is a deficit of coarse. Arrangements are legion, and comparative performance data lacking.

a Sand, iron scale, centrifuge cake, flotation concentrate.

Dry-process blending. In dry plants the raw materials, including sand and iron, usually are proportioned after crushing, but before grinding, by automatic weighing feeders. The raw ground mix is then thoroughly mixed by a blending system to average slight variations in the chemistry. The best procedure is to maintain continuous automatic sampling of the stream of ground raw mix going to raw-mix storage, resetting the grinding mill feeders, as necessary. An interval of high analysis followed by one of equally low analysis, or *vice versa*, will average off in drawing from storage, if the feed to storage has been in a succession of thin layers, since the draw tends to cut down vertically through the layers.

Fuller-Kinyon system of dry blending (Fig. 4) may be made automatic. Ground raw mix from mills *a* is discharged continuously into a screw conveyor *b* and thence by a Fuller-Kinyon dry pump *c* (see Sec. 18, Art. 11), which discharges through line *d* into the top of the raw-storage silos *e*. (Note that with the piping as arranged either row of silos may constitute raw storage.) Discharge from *d* should alternate successively into the three silos *e* for time intervals short enough to lay down each increment to a depth of not more than 12 in. Blending and mixing are effected by drawing from silos *e* into screw conveyor *f*, which delivers by cross screw *g* into dry pump *h*. This pump next delivers, again in alternate thin layers, into silos *i*, through line *j*. Drawing these again cuts across the layers, effecting further mixing. When the composition in silos *i* is right and the mixture uniform, they are drawn again through screw lines *k* and *l* into pump *h* and sent through line *m* to the kiln-feed bins *n*. By using electro-pneumatic valves on time control this system can be made automatic, subject, however, to maintenance of an over-all constant average composition of raw mix flowing in line *d*.

Cost of operation (excluding all overhead) of a Fuller-Kinyon dry-blending plant is about 0.0075¢ per bbl. of cement when handling 50 short t.p.h., including pumping from the blend bins to the kiln-feed boxes with 200% circulating load.

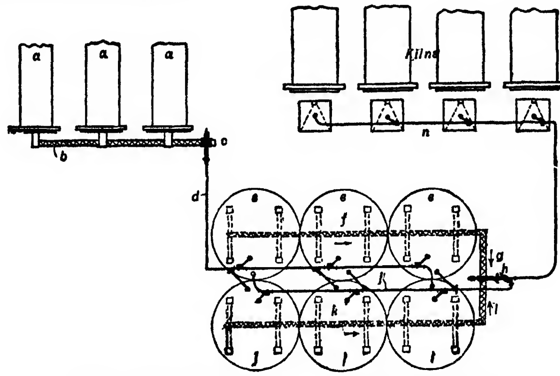

Fig. 4. Dry-process blending, Fuller-Kinyon system.

HEAT TREATMENT

Heat treatment is the essence of cement manufacture; the steps preceding it are common to many other processes and characteristic of none; those following are even less distinctive.

Heat treatment comprises both heating the prepared mix at such a rate, to such a minimum temperature, maintained for such a time, that the desired reactions will occur, and then cooling at such a rate as to control the crystallization and transformations of the resulting compounds.

3. CHEMISTRY OF THE KILN

Heating (BURNING) is invariably carried out in a rotary kiln (Art. 4) of such length and diameter, and run at such a speed, that, at the temperatures prevailing, time is allowed for completion of the principal conversion reactions. The kiln reactions, in order of occurrence, are: (1) evaporation of uncombined water; (2) dehydration of clay and calcination of $MgCO_3$; (3) calcination of $CaCO_3$; (4) reaction between the solid oxides. Since each of these reactions requires a higher temperature than the one preceding it, the kiln is fired at the discharge end, so that the stream of material flows through successively hotter zones. Fig. 5, based on thermocouple measurements, gives approximate gas and solid temperatures in a 10×200-ft. wet-fed kiln (*10 Z 581*). It may be taken as generally representative of the temperature variations in the different zones in any kiln.

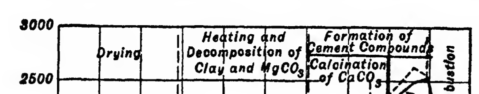

Fig. 5. Temperature-distance curve in a typical wet-fed cement kiln.

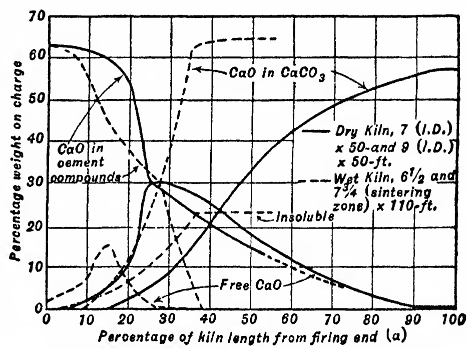
Evaporation is a problem in drying (Sec. 17). The special problems met in the cement kiln are the fineness of the solid and the liquid character of the feed, which results in failure to shower. GAS VELOCITIES are about 15 f.p.s. maximum, usually about 10 f.p.s. Surface exposure is obtained by chains hung to the inside of the shell (see Fig. 7). These become coated with thin layers of slurry, which, of course, dry more rapidly than a stream flowing along the bottom of the shell. The drying section usually occupies 20 to 30% of the

length of a wet-fed kiln, the range being determined by the effectiveness of the means for increasing drying surface; little or no drying time (and length) need, of course, be provided for dry feed. Heating in this section is substantially all by conduction; radiation is practically completely shaded off by dust. Gas temperature is such as to give a stack temperture of 350 to 500° F., this relatively high range being maintained to insure against condensation in the flue system, with consequent high corrosion. Despite the relatively large mean temperature difference prevailing in the drying section, heat transfer tends to be low with wet feeds. Solid temperatures in this section rise but little above 212° F., due to the high latent heat of evaporation of water.

Heating section occupies another ± 30% of the effective kiln length. With means for closer measurement there would be small breaks in the solid-temperature line (Fig. 5) corresponding to the absorption of heat by the endothermic reactions of calcination of $MgCO_3$ (at about 750° F.) and of dehydration of the clay (at about 930° F.), but owing to the relatively small quantities involved, these do not affect the average slope of the heating curve appreciably.

Calcination of $CaCO_3$. The vapor pressure of CO_2 in $CaCO_3$ (DECOMPOSITION PRESSURE) reaches atmospheric pressure at about 1650° F. The reaction is endothermic and involves a large percentage of the solid in the kiln. Hence for a considerable time (about 15%, Fig. 5) substantially all of the heat input to the solid is consumed in driving this reaction, the temperature of the solid remains substantially constant, and the gas temperature drops sharply through loss of the absorbed heat. Fig. 6 generalizes composition analyses of samples so taken as to be as nearly as possible representative of the material at different points in relatively small wet and dry kilns (*18 Z 886; 24 IEC 332*). Calcination in the wet kiln starts between 60 and 65% of the distance from the feed end and corresponds reasonably to the showing of Fig. 5 (in a different wet kiln). The start is shown to come much earlier, of course, in the dry kiln. Both the wet and dry curves of Fig. 6 indicate that the inference drawn in zoning the kiln in Fig. 5 is not wholly justifiable, but that reaction to form cement compounds starts as soon as any lime is freed, and that while the 76% point of length in Fig. 5 may mark the end of substantial calcination, it does not mark the beginning of reaction. Free lime does not appear in appreciable amounts until the decrease in acidic reactants, plus the acceleration in calcination, caused by additional heat from the cement reaction and close approach to the radiant zone, causes the rate of calcination to surpass the rate of reaction. The free-lime content then passes through a maximum, from which it falls rapidly with exhaustion of $CaCO_3$.



Note: Kiln length and time are not interchangeable as ordinates, owing to changes in kiln diameter.

FIG. 6. Reaction-distance curves for cement kilns.

Cement reaction. The principal and controlling ingredients of all cements are CaO, SiO_2, Al_2O_3, and Fe_2O_3. These, all in finely divided solid form, undergo first solid-solid reactions in the kiln, and later, reactions in a partial melt to form the four major compounds: C_3S = tricalcium silicate ($3CaO \cdot SiO_2$); C_2S = dicalcium silicate ($2CaO \cdot SiO_2$); C_3A = tricalcium aluminate ($3CaO \cdot Al_2O_3$); and C_4AF tetracalcium aluminoferrite ($4CaO \cdot Al_2O_3 \cdot Fe_2O_3$). The relative and absolute proportions of these compounds are, as has been developed (Art. 1), controlling in determining the character of the resulting cement; what these proportions will be in any case is determined in large part by the proportions of the mix, but burning temperatures and cooling rates also have an effect.

Calculation of compounds. The existence of the cement compounds and their mineralogical identities has been established by the microscope and X-ray, by segregation and chemical analysis (*27 IEC 312*), and by phase-diagram studies based on approximations to melting points (*40 Pro. ASTM 988*). The method of estimation of the relative quantities of each from an oxide analysis, as originated by Bogue (*1 IECA 192*), follows:

1. Estimate C_4AF from total Fe_2O_3. Ratio $C_4AF/Fe_2O_3 = 3.04$.
2. Deduct Al_2O_3 in C_4AF from total Al_2O_3. $Al_2O_3/Fe_2O_3 = 0.64$.
3. Estimate C_3A on remaining Al_2O_3. $C_3A/Al_2O_3 = 2.65$.
4. Deduct sum of free CaO shown in analysis and CaO in gypsum, C_4AF and C_3A from total CaO on analysis. $CaO/SO_3 = 0.70$; $CaO/C_4AF = 0.46$; $CaO/C_3A = 0.62$. Call this C_R.

5. $C_3S = 4.07C_R - 7.60S$ ($S = \%SiO_2$ in cement).
6. $C_2S = 8.60S - 3.07C_R$.
7. $CaSO_4 = 1.70(SO_3)$.
8. MgO = same as in cement.
9. Loss = same as in cement.

Lea and Desch (*Chemistry of cement and concrete, 117*) propose the following corrections to the Bogue estimates. They assert that the composition thus corrected is accurate within ±2% for a clinkering temperature of 1,400° C., and that the figures are not much affected by higher clinkering temperatures, but may be if the temperatures are much lower than 1,400°. Let $x = \%Al_2O_3$ in cement and $y = \%Fe_2O_3$. For $x/y = 0.9$ to 1.7, no correction. For $x/y = 1.7$ to 6.1, add to the Bogue values for C_3S the quantity $(1.8x - 2.8y)$; for C_2S, $(2.1y - 1.4x)$; for C_3A, $(2.5y - 1.6x)$; for C_4AF, *nil*. C_5A_3 may also be expected in the amount $1.2x - 1.8y$. Negative correction values are to be added algebraically.

Composition figures ordinarily given in the literature are original Bogue figures uncorrected. Neither these nor the corrected figures represent the compound composition when cooling of the clinker is so rapid as to freeze considerable proportions of clinker liquid as a glass.

Corresponding analyses of raw mix, clinker, and cement for several typical type cements are given in Table 19.

Table 19. Typical analyses for type cements

Formation of cement compounds. Prior to the presentation of the evidence described in the preceding paragraph, the beginning of the reaction zone was customarily placed at the break in the heating curve at about 1,750° F. (Fig. 5). The rapid temperature rise beginning at this point is due to the exothermic character of part or all of the compound-forming reactions (±180 B.t.u. per lb. of clinker; *11 Z 245*). The next break, at about 2,280° F., marks the beginning of fusion of the cement compounds and the beginning of clinker formation. The fall in rate of temperature rise, here in the hottest part of the kiln, is due both to the absorption of heat of fusion and to depletion of the supply of the reactants which have been contributing reaction heat to the sensible-heat supply.

The final break in the temperature curve marks completion of the exothermic reaction and cessation of that heat supply, passage beyond the combustion zone and contact with the cool gas supply, and absorption of further heat of fusion from the hot solid.

Size of raw mix. Initial cement-forming reactions are of solid-solid type. Hence they are limited to points of contact between the reactants, and subsequent reaction can proceed only so fast as the initial reactants or the intermediate reaction products can diffuse through the solids. It follows that initial reaction rates are dependent upon the sizes of the particles in the raw mix, since these determine not only the number of points of reaction but the linear distances through which diffusion must take place before complete conversion can occur. The burnability of a mix increases with decrease in size down to about 20-μ, but the rate of increase falls markedly at about 60-μ. Since the difficulty and expense of grinding increase rather markedly as the limiting size approaches 60-μ, plant costs determine how far it is advisable to go in size reduction. At the old limiting size of 100-m. (147-μ), excessive kiln temperatures and long times were necessary to insure complete burning, especially when, as was normally the case, the coarsest grains were quartz and mica.

Burnability of kiln feed can be checked and controlled by a simple laboratory test which consists in burning small pellets of kiln feed in a globar-type electric furnace capable of holding plant kiln temperatures, test time-factor being made comparable to the time-factor in the hot zone in the plant kiln. Burned test clinkers are then subjected to analysis for uncombined calcium oxide, the known limits for which have been established by plant practice and corollary tests. Regular performance of this test uncovers any changes in burning characteristics of kiln feed. Curves such as those shown in Fig. 6A, readily established for a given plant, make it possible to locate the causes of such changes with considerable precision.

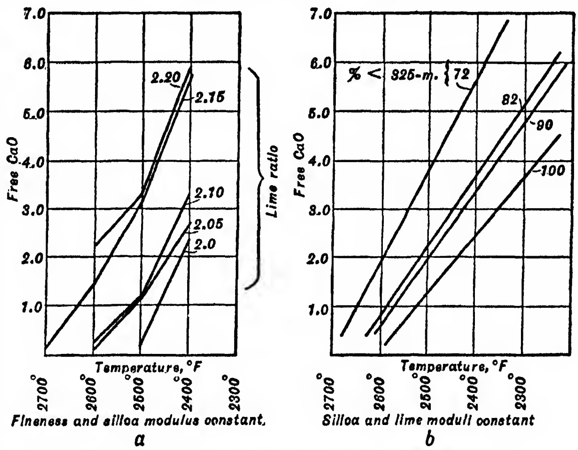

FIG. 6A. Burnability curves for VALLEY FORGE CEMENT CO. (*after M. D. Olver, PC*).

4. BURNING

Rotary kiln (Fig. 7) is invariably used. It is a rotating open-ended cylindrical shell *a* with its ends projecting into fixed feed and discharge structures. Shell diameter ranges from 6 to 15 ft. and length from 60 to 500 ft.; predominating diameter in modern plants is 10 to 12 ft.; length averages 350 ft. Diameter is frequently enlarged through a portion of the length near the discharge end in order to give increased time-factor for calcination and reaction.

Shell *a* is of 1/2- to 1-in. steel plate, riveted or welded, and lined throughout with fire brick, varying in character at different points. It is mounted, at a slope of 3/8 to 5/8 i.p.f., on hardened-steel tires *b* and rollers *c*, support piers being spaced 60 to 75 ft. apart, according to the weight of the shell and allowable loads for the type of roller chosen. One or more thrust rollers are provided. Drive is usually by d.-c. motor *d* with reducing gear *e* and flexible coupling *f* to a pinion *g* and ring gear *h* (with or without intermediate gearing *i*), the assembly being suitably mounted near the halfway point of the shell length to reduce torque. SPEED is in the range of 10 to 35 f.p.m. peripheral inside lining. LINING is ordinarily alumina brick, 70% Al_2O_3 for the clinkering zone and 50 or 60% elsewhere; magnesite brick is sometimes used in the high-temperature zones. Thickness is 6 to 9 in., depending largely upon the diameter of the kiln. A layer of Sil-O-Cel or asbestos insulating brick may be laid between brick and shell in the preheating and calcining zones. Life of lining in the hot zones is in the range of a few weeks to two years; with suitable brick for the particular rock and with careful operation, life should not be less than 6 mo. Chemically bonded magnesite lining, which may cost $100 per ft. of kiln against $40 per ft. for 70%-alumina brick, is reported (*41 #4 RP 82*) to have lasted 1 yr. *vs.* 3 mo. for the brick. Slope averages 7/16 i.p.f. in modern kilns; it averaged 9/16 i.p.f. in the period 1927–1931.

Feed-end housing serves the purposes of introducing feed, collecting dust, and acting as a junction in the gas-flow line between the shell and the flues leading to the stack. In the kiln shown in Fig. 7 the housing comprises a light paneled-steel smoke box *j*, suitably lined for insulation and protection against corrosion, with provision as shown for a slurry-feed pipe, having a hopper bottom for drawing off col-

lected dust, and a side outlet to the stack, usually via an exhaust fan. The end of the shell projecting into the smoke box is provided with peripheral gas outlets *k*, which serve to decrease gas velocity through the collared-down end of the shell. A rubbing ring *l* on the outside of the shell, against which fixed packing held in a ring on the face of the smoke box bears, forms a seal. Measuring pot *m* is so proportioned and box *n* so baffled as to seal against gas escape in this direction. With dry feed, an enclosed star feeder (Sec. 18, Art. 22) or the like is used as a seal on the feed line.

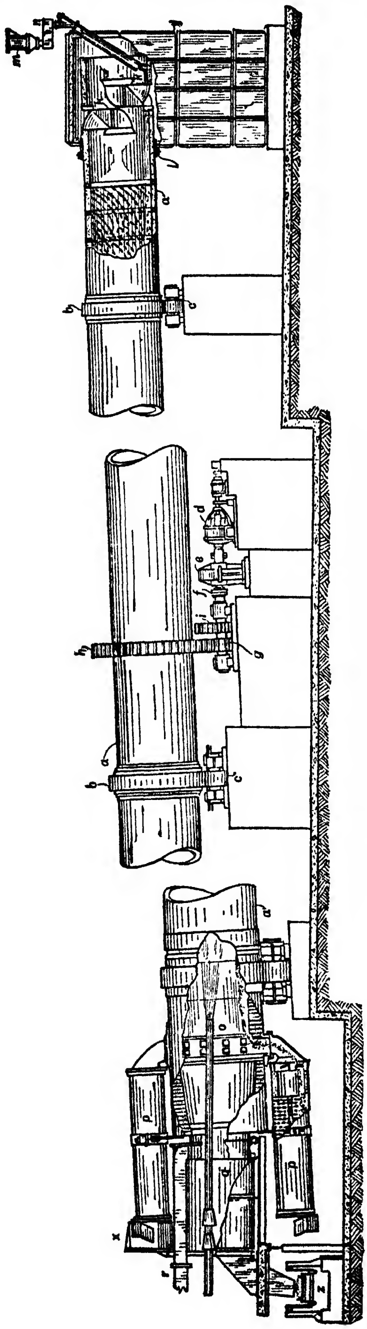

Fig. 7. Rotary wet-feed kiln (*after F. L. Smidth & Co.*).

Discharge-end housing provides for discharge of clinker and introduction of fuel and air. In the form shown in Fig. 7, clinker discharges through ports *o* near the end of the shell to a Unax cooler *p* (p. 23). The kiln shown, arranged for burning powdered coal, has an end shield *q* with an outer shell at one end to provide an air-heating conduit through which air may be forced and thus pass via conduit *r* to dry the coal.

Fig. 8 shows an arrangement of apparatus and piping for the firing end of an oil-fired kiln using the heat in the clinker for preheating secondary air. Clinker discharges from the end of the kiln against baffle wall *a* and thence onto grate *b* of a reciprocating-grate cooler. Secondary air, blown in by fan *d*, enters under grate *b* into a chamber defined by the floor of the cooler and a transverse baffle under the grate at *e*, and passes up through the grate and hot clinker and thence behind baffle *a* into the discharge-end housing and into the kiln. The suction pipe *f* for the primary-air fan *g* opens into the discharge housing, and is also branched to the atmosphere, with a temperature-controlled damper at *h* for proportioning the supplies to fan *g* to maintain the desired temperature. Primary air delivers through pipe *i* to the blast pipe *j*. Fuel-oil pump *k* takes suction through line *l* on the supply tank and delivers through exchanger *m*, in exchange with steam from boiler *n*, and thence through meter *o* to the burner. Additional air for final cooling of clinker is delivered by fan *p* and a floor flue under the discharge end of the cooler grate and passes to stack *c*. Cooled clinker is transferred on shaking conveyor *q* to clinker pit *r*.

Air temperatures. Primary air for coal firing with unit mills ranges from 100 to 170° F.; with coal pulverized in a central station and fed from bins, it is held at 200 to 250° F.; with fuel oil it varies. Secondary air, using recuperator coolers, ranges from 900 to 1,000° F. Saving in fuel from such preheating is about 20% maximum.

Drying section. Fig. 7 shows an arrangement of chains hung from cast-iron liner rings, which are used to elevate and suspend wet slurry in relatively thin films in the path of the hot gases. Chains are of 1/2- to 3/4-in. steel rod, in links about 2 in. wide and 3 in. long. In the 350-ft. kiln illustrated the chain system would extend 75 or 80 ft. and would save an additional 70 or 75 ft. of kiln length, with an economy in fuel consumption of 11 or 12%. Fuel saving may be 15 to 18% when chains are installed in a shorter kiln. Wet kilns are frequently provided with lifters and a framework extending across the kiln section, the combination serving to shower the material through the gas stream. Short kilns are inefficient unless special equipment, to facilitate heat transfer, is used (*e.g.*, the Grudex or Lepol system) or unless used with waste-heat boilers, when the power thus generated compensates for the inefficient use of the heat in drying. When electric power is purchased, some efficient form of drying should be used perforce, if a plant is situated in a competitive area.

Feeding of wet slurry is usually done by a regulating feeder of the Ferris-wheel or spiral-scoop type

taking from a constant level tank in circuit with a surge tank. Delivery is through a measuring pot and gas seal as described above. Dry mix is usually fed by screw conveyor.

Fuel is largely a matter of availability. Of 20 kilns in recent plants, 14 use powdered coal, one oil, and the remainder natural gas. It is customary, however, particularly where the fluid fuels are locally available, to provide for using either of these and, usually, for

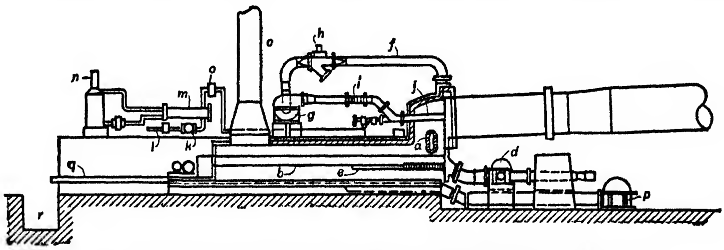

Fig. 8. Arrangement for heat recuperation (*after Allis-Chalmers Mfg. Co.*).

powdered fuel also. Draft may be obtained either by suction fans or by stack. The former method provides the more uniform draft and insures sufficiency at all times. Fuel consumption in an efficient wet kiln with instrument control and recuperator coolers is about 1,000,000 B.t.u. per bbl. of cement. Of this 50 to 55% is used for evaporation of the water from slurries containing about 35% moisture. Average consumption for less modern kilns with coal firing is 90 to 100 lb. of 13,500 B.t.u. coal per bbl. of cement.

Distribution of heat consumption in a wet-process kiln with Unax cooler is shown in Fig. 8A.

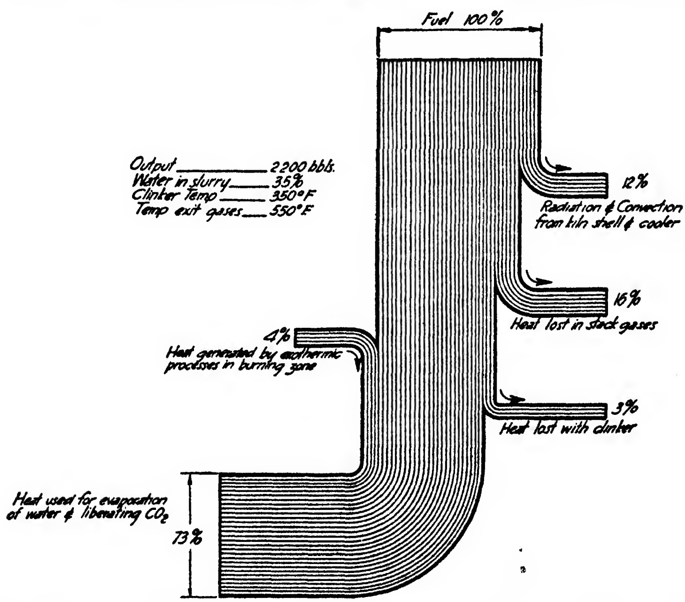

Fig. 8A. Graphic heat balance of wet-process rotary Unax kiln-cooler unit (*after F. L. Smidth & Co., PC*).

Capacity of a kiln is an intricate time-temperature-efficiency integral which is also dependent upon the size of the feed and the effectiveness of the premixing. Evaporation of free water and preheating of the dried solid to the calcination temperature of the limestone are limited in rate only by the supply of available heat and the efficiency of heat transfer, but both the calcination and the reactions to form the cement compounds are solid reactions diffusion-controlled; therefore although the surface reaction rates increase exponentially with increase in temperature, continuance of the reaction by diffusion is by

no means proportionately accelerated. The practical means of acceleration are: (1) decreasing particle size to increase the surface available for immediate reaction and to lessen necessary diffusion distances, and (2) increasing the extent of fusion whereby the increased mobilities of reactants and reaction products characteristic of solution reactions are obtained.

Apart from fineness of feed and thorough preliminary mixing, the expedients employed to increase capacity are: (1) filtration of feed, or provision of chains in the drying zone; (2) insulation of the preheating zone; (3) increase in diameter through the zone of calcination and insulation thereof; (4) control of flame in the clinkering zone and as rapid turnover of charge as is possible to effect maximum utilization of radiant heat.

It follows from the preceding discussion that the kiln must provide certain minimum times for the four principal operations or reactions; that the temperature conditions and necessary times for each are different; and that capacity of a kiln is a matter of the quantity of material that can be subjected effectively to such operations at one time. Time in the kiln is a matter of length of path and speed of pulp travel. Length of path is determined by length and diameter of kiln; speed is a function of pitch, r.p.m. and diameter. Volume that can be presented effectively to the heating means depends upon diameter of kiln, rate of turnover of charge, and the ratio of surface of the traveling stream to its volume. Maximum capacity is attained when the stream volume is the maximum that can be treated effectively in the minimum reaction time imposed by the size of feed particles.

Large modern kilns have capacities as high as 4,500 bbl. per 24 hr., as against 200 bbl. per day for the 6×60-ft. kiln of the early 1900's.

Size of kiln may be estimated as follows: For preheating, calcining, and clinkering allow 3.5 sq. ft. of inside surface per daily barrel of cement for easy-burning mixes; allow 4 sq. ft. for mixes of high lime factor or coarsely ground. These figures are for short kilns (about 125-ft.) with high (1,400° F.) exit-gas temperatures. In such kilns the preheat zone is 20 to 30 ft. long, the calcination zone 60 to 80 ft., and the clinkering zone 30 to 40 ft. For wet kilns add a minimum of 30 to 50 ft. for drying. Burning zone is made shorter when air quenching is practiced, since such kilns are fired to the nose to discharge clinker at full heat. When exit gas temperatures of 400 to 450° F. are desired, the evaporating and preheat zones are lengthened materially. In a recent Puerto Rican kiln 75 ft. was allowed for drying, 110 ft. for preheat, 62 ft. for calcining, and 48 ft. for clinkering. Average diameter of kilns built 1932 to 1942 was 10.4 ft.; average length, 330 ft.

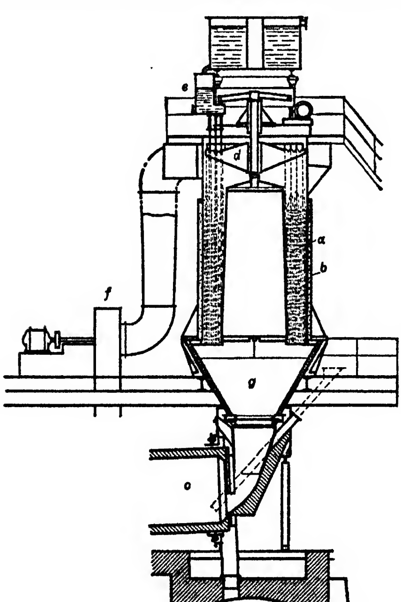

Fig. 9. Vertical-chain slurry drier.

Predrying of wet feed is practiced at some plants. It permits the use of shorter kilns; it increases the capacity of a short kiln; it makes the flue gas available for steam generation; and, with a well-designed drier, evaporates water more economically than can be done in a kiln.

Filtration (Sec. 16) removes enough water to permit the use of flue gas for waste-heat steam generation. The filter is usually placed on the feed floor, with cake falling directly to the kiln feeder.

Polysius vertical-chain drier (Fig. 9) comprises a network of chains *a* hung in a cylindrical annulus in an insulated tower *b* located above the feed end of the kiln *c*. The chain support *d* is arranged to rotate slowly. Slurry from a supply tank *e* is sprayed onto the chains over a part of the annulus through pipes depending from the feed tank. Gas is drawn from the kiln upward through the annular space and chain mass by a fan *f*. The wet slurry on the chains is slowly revolved out of the spray into a drying zone where water evaporates both through the direct heat from the hot gases and by heat transferred from the chains heated in their preceding pass through the later part of the drying zone. As the material dries sufficiently to fall off the chains it is balled up by the chain action and finally falls clear into hopper *g* and thence into the kiln. Gas as hot as 1,400° F. can be handled. Exit gas is usually between 130 and 300° F. The partly dried slurry contains from 5 to 13% moisture (*PQH*).

Miag calcinator comprises a gratelike slowly revolving cylinder about 13 ft. in diameter by 10 ft. long, set horizontally in a housing so conformed as to force rising gas to pass through the grate openings (about 3 in. between grate-bar faces). The cylinder is about half filled with lengths of pipe lying with long axes parallel to the drum axis. Slurry is fed in at the top. Kiln gas enters at the bottom and is drawn through by a fan. The partly dried slurry discharges in the form of nodules containing about 10% moisture and falls into the kiln. Temperature of exit gas is claimed to be about 200° F. (*PQH*).

Preheating of dry mix has not been practiced to any considerable extent in the United States, probably because of the extensive use of waste-heat boilers. Thus in recent modernization of the Pennsylvania-Dixie plant at Nazareth, Pa. (*35 #1 PQ 53*), instead of preheating, waste-heat boilers were installed which provide sufficient power to run the entire plant with an over-all fuel consumption of about 1,050,000 B.t.u. per bbl. New insulated kilns with modern grate coolers (Fuller) and unit mills to dry and pulverize coal were installed.

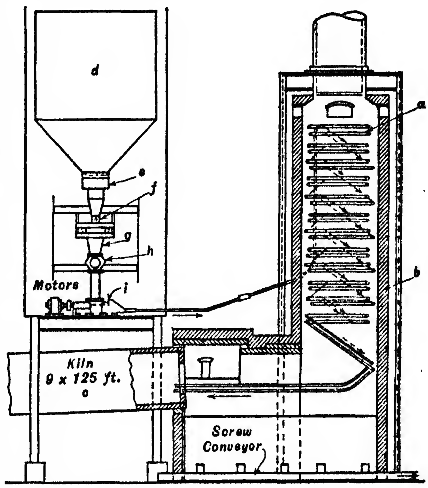

Fig. 10. Grudex system of preheating dry mix.

Grudex system (Fig. 10) is used at Coplay Cement Manufacturing Co., Coplay, Pa. It comprises a countercurrent coil consisting of 1,200 ft. of 4-in. chrome-nickel steel tubing *a* arranged in circular coils in a vertical flue *b*, receiving waste gas from the kiln *c*. Raw mix from bin *d* passes through a weigh-gate *e*, feeder *f*, surge hopper *g*, roll feeder *h*, and Fuller-Kinyon dry pump *i*, through the coil and thence to the kiln at a temperature of about 1,400° F. Power consumption is claimed to be about 0.7 hp-hr. per bbl. of cement (*U. S. Pats. 1,801,467; 1,961,311*).

Lepol system (Fig. 11), used largely in Europe, is designed to supply preheated dry mix to the kiln in nodular form. The raw mix from bin *1* discharges into elevator *3* and thence through surge bin *4* into a revolving drum *5*, in which the material is sprayed lightly with water and delivered as small nodules through a feed hopper *6* onto an endless traveling grate in the enclosure *7*. Exit gas from the kiln *8* at 1,600 to 1,800° F. is drawn down through the grate by fan *10* and discharged through stack *11* at 250° F. Dust collects in hoppers *12* and is returned via screw *13* to elevator *3*. Stack *14*, with an umbrella lock, is used for starting only. Coal-dust firing from bin *16* is illustrated,

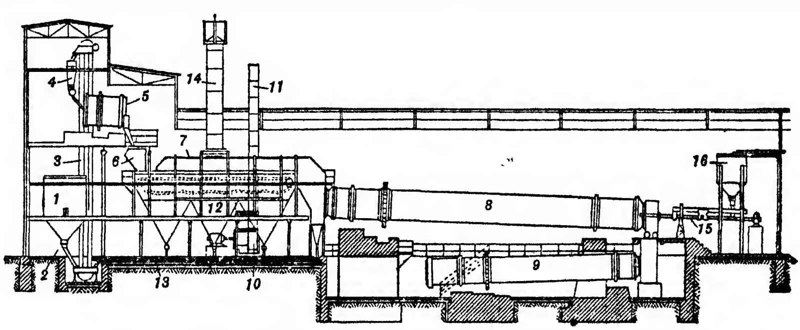

Fig. 11. Lepol arrangement for preheating feed.

but fluid fuels may be employed. The pellets, partly calcined and containing from 8 to 12% moisture, fall into the kiln from the end of the grate. Fuel consumption as low as 682,400 B.t.u. per bbl. of cement is claimed (*PQH*).

Cooling

Clinker is cooled primarily to permit storage and facilitate handling, but controlled machine cooling, including an initial air quench, has secondary results that are equal or more important. Thus much of the heat in the clinker is retained and returned to the kiln, the clinker is embrittled and rendered easy to grind, and the physical nature of the cement

compounds is so affected as to decrease grain size and improve the autoclave test. Cooling is almost invariably done with air, which is inert to the clinker and is the cheapest supply. Two methods are employed, *viz.*, rapid cooling (AIR QUENCHING) or slow gradual cooling.

Coolers may be classified into three principal types: (*a*) slow; (*b*) recuperator; (*c*) air-quenching.

Rotary cooler is slow, and therefore recovers a considerable part of the heat from the clinker. Feed is ordinarily direct from the kiln. Size is determined by the type of the kiln it is working with, and the quantity of clinker to be cooled. Design and construction follow those of the kiln, using tires and rollers for support, with ring gear and pinion drive. The upper end of the cooler is lined with suitable firebrick to protect the shell against excessive heat, and lifters are used to facilitate air contact with the clinker.

Size of cooler for a capacity of about 2,200 bbl. per day is estimated by F. L. Smidth & Co. (*PC*) at 12×120-ft.

Recuperator coolers. UNAX (F. L. Smidth & Co.), in general use, is shown in Fig. 7. It comprises a plurality of small cylinders *p* attached to the kiln shell and arranged to discharge at the top of their revolution into a hopper *x* delivering by chute *y* to clinker conveyor *z*. Tubes *p* may be arranged in single or double rows. The average-size kiln has 10 @ 4-ft.-10-in. (diam.) × 20-ft. units in a single ring. Each unit has a chain heat-transfer system with about 2,400 ft. of 3/8-in. chains. Secondary air is delivered at 900° F., and clinker is discharged at 400° F. Draft from the kiln draws atmospheric air through the cylinders.

Vanderwerp cooler (Manitowoc Engineering Works) is attached to and is an integral part of the kiln. It preheats combustion air and cools the clinker by blowing the air through louvred liner plates (see Sec. 17, Fig. 10). Air may be controlled to eliminate excess combustion air. Clinker is discharged at a temperature of about 700 to 800° F., and must be after-cooled if cold clinker is desired.

Air quenching coolers are of grate type (Fuller Company) and pan type (Allis-Chalmers). The method used to air quench is to supply air in sufficient volume to cool the clinker rapidly in its liquid phase, in order to convert some of the compounds into a glasslike structure. This type of cooler is also an excellent heat recuperator.

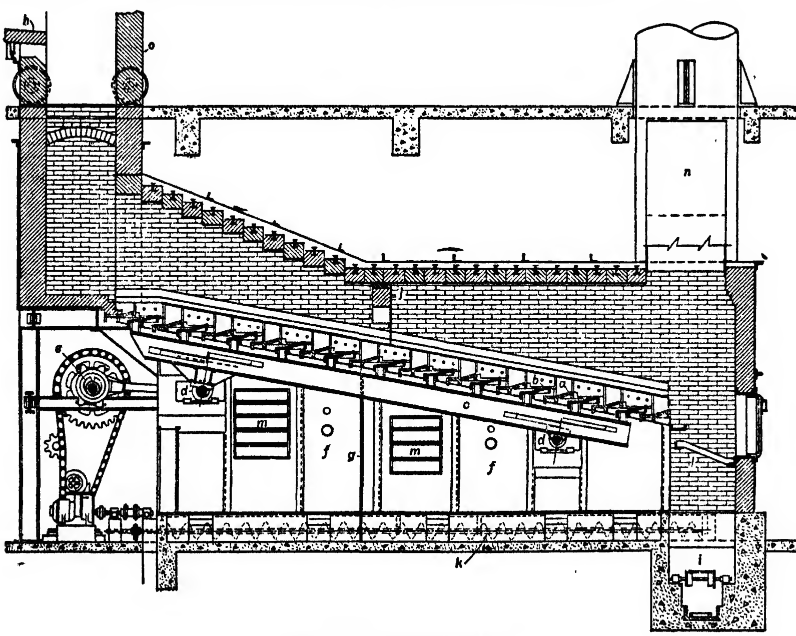

FIG. 12. Fuller grate cooler.

Grate cooler (Fig. 12) consists of an inclined (−10°) movable stepped grate mounted as a perforate diaphragm across a large air duct in such a way that air passes upward through the grate and a bed of clinker travels down it, cooling the clinker and being itself heated.

In the form shown, the perforated grate bars *a* (hatched) are fixed, and the movable bars *b* (black) are mounted on structural-steel frame *c*, carried on wheels *d*, and oscillated by chain-driven eccentric *e*. This assembly forms the roof of sheet-steel-walled plenum chamber *f*, divided by partition *g*. The space above the grate comprises a bricked-in flue and clinker passage, connecting at the upper end with kiln *h*, through hood *o*, and at the lower end with a conveyor *i* for cooled clinker. This flue is likewise partitioned at *j*. Clinker travels down the grate by the push-feeder action (Sec. 18, Art. 22) of the moving grates, which alternately push material off the stationary grates onto themselves (forward stroke), and are themselves unloaded by the push of the stationary grates (back stroke). Screw conveyor *k* removes spill, as necessary. Grizzly *l* is set to hold back occasional large lumps only.

Air enters from a centrifugal blower in streams regulable by inlet dampers *m*. More air is required for cooling than is necessary in the kiln; hence the cooler air, comprising the excess, is discharged through stack *n*. The cold air passing through the hot clinker at the upper end quenches it at a rate depending upon the depth of the clinker bed and the volume of air flowing through this portion of the grate; these may be controlled automatically.

Typical data follow: Cooling 2,000 bbl. per day from 2,500° F. to 150° F.; kiln fuel, 1,000,000 B.t.u. per bbl., grate area, 6 × 20 ft.; air, 26,000 cu. ft. per min. at 6 1/2 in. H_2O under the grates and 9 in. H_2O at the fan; fine clinker in 4- to 5-in. bed in cooler 10 to 15 min.; air to kiln, 1,200° F., 264,000 B.t.u. per min. or 190,000 B.t.u. per bbl.; air to stack, 275° F.

Pan cooler consists of a grate, forming the bottom of a trough which is hung horizontally in a wind box, and is reciprocated between 250 and 300 @ 3/4-in. s.p.m. on a Ferraris suspension (Sec. 11, Art. 16) suitably spring-balanced. Depth of bed is controlled by automatic variation in speed of the driving motor with back pressure on the air. DIMENSIONS vary according to the service, *e.g.*, a 5 × 10-ft. machine to air quench only, supplemented by rotary cooler to reduce clinker temperature to an extent suitable for feed to the grinding mills; and a 4 1/2 × 55-ft. machine for both quenching and final cooling. The latter machine, loaded, requires a large and heavy drive and is probably close to the size limit for this type of machine.

Action in a quenching cooler. Embrittlement of clinker is effected by cooling at such a rate that the fused part solidifies to form a brittle glass. This has the effect of rendering the glassy material itself easier to grind and also weakens the bond between the grains nonfused in the kiln. Air quenching also changes certain qualities of the cement. The special types (A.S.T.M. Types 2, 4, and 5, and the equivalent Federal types) were designed to lower autoclave expansion, decrease heat of hydration, and increase resistance to aggressive waters by increasing total lime silicates and reducing MgO, and alumina and iron compounds (C_3A and C_4AF). Air quenching helps to accomplish the desired ends by physical rather than chemical means, and is particularly useful when the undesired compounds tend to form in excess. The C_3A and C_4AF are in liquid phase at the clinkering temperature (2,600 and 2,800° F.). When the clinker is cooled quickly, a large portion of these compounds is converted into an amorphous glasslike structure, in which form the undesirable properties of the compounds largely disappear. If, therefore, the specifications intended to cover heat of hydration and sulphate resistance are satisfied by means of physical tests rather than chemical, greater latitude in processing and blending is possible.

Cost of kiln operation is usually the largest cost item in cement manufacture. The principal cost elements are fuel, labor, and maintenance. Despite a trebling of fuel prices and quadrupling of wages since 1914, and a radical increase in prices for maintenance material and supplies, the direct manufacturing cost of cement in well-run plants, until very recently, has been kept down to a remarkable degree, while the quality of cement has greatly improved. The factors in this paradox are: (1) a decrease in fuel consumption from about 1,850,000 to 1,000,000 B.t.u. per bbl. for wet kilns; and from 1,350,000 to 1,050,000 B.t.u. for dry kilns, at the same time providing sufficient recovered heat to manufacture power enough to run the entire plant. (2) A radical reduction in man-hours per barrel to offset the increase in wage rates; this was done by the use of large burning and grinding units and various labor-saving machinery. (3) Increase in knowledge of the chemistry and physics of heat treatment. (4) Development of automatic, *i.e.*, instrument, control.

Fuel consumption was improved by recovery of heat from clinker, and by performing the drying and preheating operations outside the kiln or, by insulating these sections of the kilns and by use of chains, improving heat absorption. Better firing has been effected by automatic temperature controls. Normal consumption ranges from 80 to 100 lb. of 13,500 B.t.u. per bbl. or an equivalent heat value in oil or gas.

Labor per bbl. of cement has been reduced primarily through the use of large units; the saving in burning has, however, been increased, so far as coal-burning units are concerned, by substitution of unit (*i.e.*, individual) coal-grinding mills delivering their product dried and aerated directly to the kiln. Automatic-control devices also find their principal application in the burning department.

Man-hours for the entire clinker department (burning, cooling, and storing) for plants, either wet or dry, producing from 1,000,000 to 1,500,000 bbl. or more per yr., should not average over 0.04 per bbl.

Several large wet plants, and several modern plants using large kilns under instrument control, can produce a barrel of clinker at a consumption of about 0.025 man-hour.

Instruments found in a modern plant are: automatic controllers on draft, fuel feed, and cooler speed; recording pyrometers on burning zone, which may be linked to controllers on kiln speed and kiln-feed rate; also on secondary air, kiln exit gas, and on air in and out of coal mill; meters on kiln draft, secondary air, coal-mill air; tachometers on kiln and feeder; manometer on pressure under grate of primary cooler; automatic gas analysis.

Cost range (1942) for burning was from 26 to 33¢ per bbl. of clinker. Breakdown is shown in Table 20.

Table 20. Cost of burning to clinker (per bbl. of cement) *a*

Item	Average plant	Large plant
Operating labor	$0.0250	$0.0192
Operating supplies	0.0012	0.0008
Maintenance labor	0.0073	0.0054

FIG. 13. Typical flowsheets for clinker grinding.

5. GRINDING CLINKER

When clinker is placed in water, hydration of the particles starts immediately with the formation, in place, of a relatively insoluble gel. This gel immediately hinders further access of water to the particle surface, and quickly begins to harden, whereupon access of water to the unchanged core is further hindered, if not substantially wholly prevented. Hence clinker comprising particles of large size range has no utility as cement. Clinker grinding is designed to reduce the largest particles of clinker to a size (probably 30- to 40-μ maximum) at which the largest particles will hydrate completely before access of water is substantially shut off, and at the same time to minimize the proportion of very fine material, which hydrates and sets so rapidly that it takes an initial set before the concrete can be placed. These contradictory requirements are met by closed-circuit dry grinding. Since the size required is too fine for efficient screening, air classification is used.

Two-stage grinding is usual. The majority of recent plants use ball mills, either integral or as separate units, for the primary stage, but many use Hercules or Griffin mills (Sec. 6, Art. 2). Discharge from the primary circuit is normally controlled by a screen when the primary mill is a separate unit. Secondary grinding is almost invariably in tube mills in closed-circuit with air classifiers. Older practice was to make the ball and tube mills integral parts of a compartmented shell, the compartments, with tumbling charges of different sizes, separated by a grate. Many such mills are still in use. Fig. 13 shows typical clinker grinding arrangements. For details of dry ball- and tube-milling see Sec. 6, Art. 3.

Clinker-grinding aids are substances added to the grinding mills that tend to prevent the correlative coating of grinding surfaces and increase in grinding time. Fish-oil stearate, tallow, Vinsol resin, and colloidal carbon have been used with more or less effect. TDA, a proprietary preparation, is most used at the present time. Usual quantities added are less than 1% on the clinker. Beneficial effect appears to be to cause dispersion, as the result of which circulating loads can be greatly increased (*e.g.* from 150% circulating to 400%) with resultant increase in capacity. Decreases in grinding time of 20 to 30% are reported. Any such reagent must, in addition to its effect on grinding, be harmless in subsequent use of the cement. Carbon darkens the cement somewhat. The organic reagents tend to cause increased air entrainment in both the dry cement and the concrete mix. The effect in dry cement is to decrease capacities calculated on the accepted basis of 94 lb. per cu. ft. It is stated (*44 #1 RP 80*)

that clinkers made with such aids tested to usual specifications for soundness; worked better than otherwise; showed less scaling, because of decreased segregation during setting; and initial and final setting times both decreased.

Costs of clinker grinding (departmental only, 1942) to 1,750 sq. cm. per gm. are given in Table 21. For grinding to 1,600 sq. cm. per gm., deduct about 1.5¢ per bbl.; for grinding to 1,900 sq. cm. per gm., add about 2.5¢ per bbl.

Table 21. Cost of grinding clinker *a*

6. CEMENT HANDLING

Cement discharges from the clinker-grinding mills at temperatures ranging normally from 200° to 300° F. It retains much of this heat in storage silos for considerable lengths of time. Many users specify maximum temperatures of 125° F. delivered at the job, which usually means that the silo-delivery temperature must not exceed 140° F. Spraying the mill shells with water and water-cooling the mill-silo transport lines is insufficient to meet these specifications in most cases, even when coupled with moderate recirculation in the silos.

Fuller cement cooler (Fig. 14) was devised to eliminate the necessity for make-shift cooling. It comprises (usually) a two-unit combination consisting of an annular cement passage *a*, through which the cement is driven by spiral flights *b* carried on the thin-walled

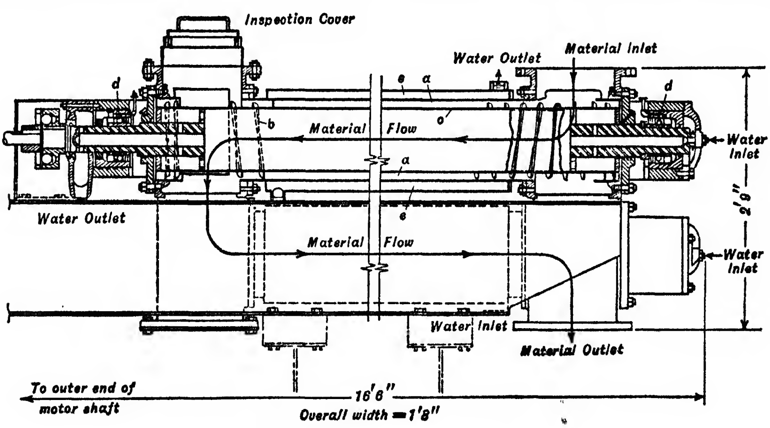

FIG. 14. Fuller cement cooler.

hollow shaft *c*, which is supported in bearings *d*, and is motor driven. Water flows through shaft *c* concurrent with the cement in the first (upper) unit, and then countercurrent through the second (lower) unit. An external cooling jacket *e* is also provided, but cooling therefrom tends to be inefficient owing to the substantially quiescent layer of cement surrounding the outer sweep of the flights. Speed is about 230 r.p.m.; motor, 5 hp. Each unit is rated at 200 cu. ft. of cement per hr.

Performance. At ALLENTOWN PORTLAND CEMENT CO., Evansville plant, with an inlet temperature of 256° F., 50 bbl. of cement per hr., and 25 g.p.m. of water at 52° F., outlet temperature from the

upper unit was 146° F.; when the second unit was added in series, the outlet temperature was 114° F. The motors drew 2.6 hp. each.

Storage is usually in concrete silos 16 to 30 ft. I.D. by 70 to 125 ft., with individual capacities ranging from 2,500 to 40,000 barrels. Such a large percentage of the cement sold must be pre-tested and stored under seal that a large number of separate bins is required; the trend, therefore, is toward bins of moderate size, *e.g.*, 2,500-, 5,000-, and 7,500-bbl. Fig. 15 shows a typical arrangement, consisting of 30 round, reinforced-concrete silos

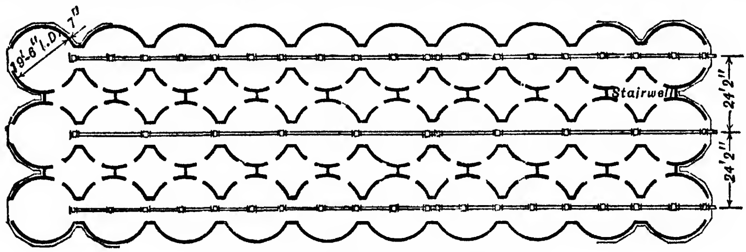

Fig. 15. Arrangement of cement silos.

19 ft. 6 in. I.D. by 70 ft. high, 17 interstice bins, and a stairwell. Capacity of the round bins is about 5,000 bbl. each; of the interstice bins, about 2,500 bbl. each (4 cu. ft. per bbl. of 376 lb.). Total capacity of the entire battery is approximately 235,000 barrels. Each bin has a conical steel bottom, side slope 50°, fitted with 14×24-in. rotary valve at the apex. All bins have flat reinforced-concrete roof slabs, suitably waterproofed.

An access basement is provided under the entire battery. Silos are filled by Fuller-Kinyon pumps (Sec. 18, Art. 11), through transport lines directly from the grinding units. A system of valves operated by remote control switches the mill stream into the desired bin or bins (Fig. 4).

Shipping. When cement is shipped in bulk, it is tapped out of the side of the silos directly into steel hopper-bottom covered cars (Fig. 16). The quantity and flow are controlled by quick-opening valves. Cars can be loaded in about 15 min.; bulk-loading tracks are provided on both sides of a battery of silos. Bulk loading is effected from silos not within gravity reach of cars (or ships) by portable F-K pumps mounted on low trucks and so arranged that the pump receiving hopper clamps to the lower end of the rotary bin-discharge valve.

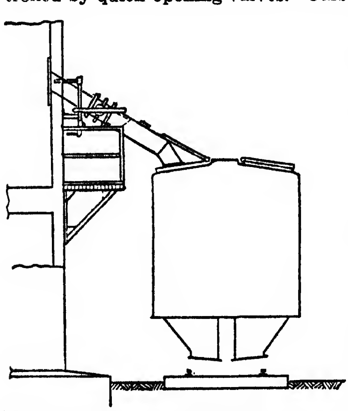

Fig. 16. Arrangement for bulk loading of cement into cars.

One pump, with 10-in. transport line, is usually provided for each row of silos. Pumps for the silo battery shown in Fig. 15 have 600 bbl. per hr. capacity each, when pumping 1,500 ft. Each pump is equipped with a 250-hp. motor, 1,200 r.p.m., and uses 2,000 cu. ft. of air per min. at 30 lb. per sq. in.

The percentage of cement shipped in bulk in 1940 was 25.6%, for 1941 it was 31%, and, considering the large government jobs under construction, for 1942 it may reach 50%. Practically all cement for big government jobs was shipped and handled in bulk.

Water shipment in bulk has developed to the point where special cement tankers are used. Boats carrying as much as 45,000 bbl. have been used on the Pacific Coast for coastwise and transocean shipment. At one plant delivery to the vessel was made by 2 @ 12-in. pump lines in parallel, 3,500 ft. long, extending 2,300 ft. over the water. Loading rate was 2,000 bbl. per hr.

Bulk unloading is done by pumps. Special unloader pumps, mounted on self-propelled trucks with complete remote control, are available for conditions which forbid the use of gravity feed.

At Grand Coulee Dam two 8-in. Fuller-Kinyon unloaders were used, each driven by a 100-hp. motor, and supplied with air by a Fuller single-stage rotary compressor delivering 750 cu. ft. per min. at 35 lb. pressure. Unloading was done at a maximum rate of 133 cars per 24 hr., pumping a maximum distance of 380 ft. into nine 5,000-bbl. steel storage tanks. Cement was withdrawn from the storage tanks, each

of which contained a cement from one mill. Withdrawal was controlled by vane feeders operating at predetermined speeds, delivering to a common screw conveyor. Blends were thus obtained homogeneous in color, chemical analysis, setting rate, and strength. From the blending silos the material was pumped to a mixing plant 7,600 ft. away by a duplex Fuller Fluxo pump, at the rate of 1,000 bbl. per hr. through 14-in. steel pipe.

Bags are filled by valve packing machines. Fig. 17 shows a typical arrangement. Cement is pumped from silos through pipe *a* into a deaerating tank *b*, whence it flows by gravity over vibrating screen *c*, which removes accidental waste, while undersize passes via screw conveyor *d* to packer-supply bin *e*. Discharge from *d* to *e* ceases when *e* is full; whereupon the excess is conveyed on to overflow bin *f*, discharge of which is controlled by valve *g*. Overfilling of *g* is prevented by an indicating BINDICATOR (level indicator) *h*, which signals the operator at the silo pump. When the level in *e* falls below that necessary to maintain the desired head on the packing machine, Bindicator *i* opens valve *g* and cement flows via conveyor *j* and bucket elevator *k* back to screen *c* and thence by *d* to *e*. Dust from *b*, *c*, *d*, *e*, *j*, *k*, etc., is drawn to dust collector *l*, which discharges collected dust into *f*. Spill from the packing machine and the bag conveyor *m* drop to *j*, as indicated. Bags coming from the packers are conveyed by belt conveyors to the car door, where they are stacked six or eight high on hand trucks to be wheeled into the car. Cars are usually lined with paper to prevent loss of spilled cement and as a protection against splinters and damp floors.

Where auto trucks are loaded, the truck usually backs under the belt from the packing machine and pulls forward as the bags are stacked on the truck and counted.

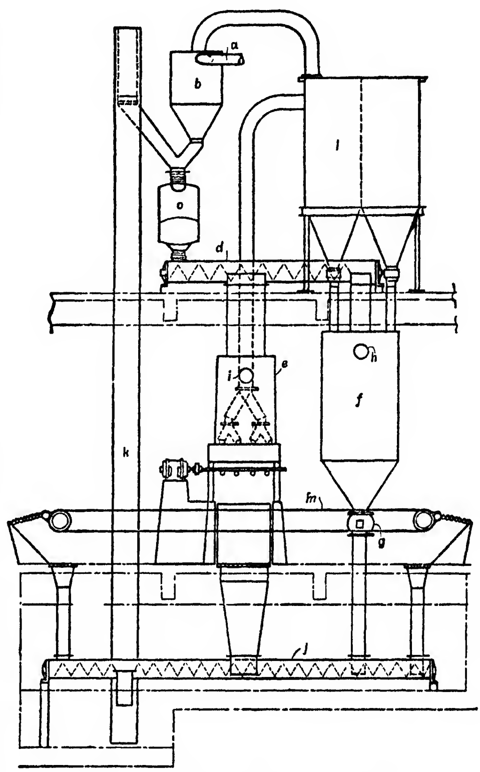

FIG. 17. Arrangement for bag packing.

Packer comprises the hopper (*e*, Fig. 17) and the bag-loading mechanism. Four housings depend from *e*, each of which encloses a feeding element consisting of a head carrying four blades clamped to a common horizontal drive shaft, driven at a constant speed of 800 to 1,150 r.p.m., depending upon the production requirements and the physical characteristics of the material. The front portion of each housing is fitted with a cap containing a discharge opening through which the cement is projected by the blades. Adjacent to each housing, but not touching it, is a filling tube carried by a frame supported on a scale beam. The operator places the valved bag on the filling tube. Cement is forced into the bag until the set weight is reached, when the automatic scale, coming into balance, allows the frame and filling tube to descend, which automatically cuts off the flow of material into the bag. As the filled bag discharges from the machine, the valve is closed by the pressure of the filling. A 4-tube machine is operated by one man and is capable of filling 1,200 or more 94-lb. bags of cement per hr.

Paper bags are supplied as single- or multiple-wall, with one or more plies of waterproof paper, if desired. They are either pasted or sewed. They are shipped to make one trip and are not returnable. In 1940, 42.5% of all cement shipped was packed in paper, 39.6% in 1941, and estimates for 1942 are about 35%.

Cloth bags are usually manufactured from 7-oz. Osnaburg, cut 30×36-in., and are tied automatically with twisted wire ties before being filled from the bottom. Cloth bags usually make from 5 to 10 trips

and are returnable at 10¢ each when in good condition. In 1940 31.9% of all cement shipped was packed in cloth, 29.4% for 1941; the estimate for 1942 is as low as 15% owing to scarcity and the high price of new bags.

Official weight of a barrel of cement is 376 lb. of cement (*ASTM C-150-41*); there are 4 @ 94-lb. bags per barrel.

Charge for packing. It is customary to add 40¢ per bbl. to the bulk price for cement, if shipped in cotton bags; 15¢ if shipped in paper. Bulk shipments are allowed 5¢ a barrel below bulk price, which is about what it would cost to pack in bags and load.

7. FLOWSHEETS

The elements of all cement-plant flowsheets are: (*a*) crushing, (*b*) rock storage, (*c*) raw grinding, (*d*) correction of composition, (*e*) burning, (*f*) clinker grinding, (*g*) storage and shipment. For details see the preceding sections. Flowsheets differ in two principal particulars, *viz.*, whether the raw grinding is done wet or dry; and whether correction is effected by addition of deficient oxides or by rejection of oxides present in excess. The latter method is done by wet classification and/or flotation and is therefore coupled with wet grinding. On the other hand, correction by addition may be employed with either wet or dry grinding, but if the amount of correction necessary is great, either because of large departures of the composition of raw rock from desired kiln-feed composition or because a considerable variety of cements is to be made, wet slurry is preferable from the standpoint of blending. Relative economies in grinding wet or dry are debated, but they are not debatable from the grinding standpoint alone; uncertainty enters on the question of the debit to be assessed against wet grinding for evaporation in the kiln. Examples of typical plants of different types follow.

Universal Atlas Cement Co., Hudson plant. Fig. 18 (*Q* by C. D. Rugen, Operating Engineer).

Location: Hudson, N. Y.
Rock: Shale and high- and low-lime limestones, susceptible of correction by blending. See Table 22.
Process: Dry.
Power: Quarrying and crushing, 3.5 to 4.0 hp-hr. per short ton; raw grinding, 22 hp-hr. per ton; burning 2.2 hp-hr. per bbl. of cement; clinker grinding (standard product), 11.5 to 12 hp-hr. per bbl.; coal grinding, 31 to 32 hp-hr. per short ton.
Fuel: Powdered coal; consumption, 75 to 85 lb. per bbl. of cement.
Running time: Rock mill, 95 to 96%; kilns, 94 to 95%; clinker grinding, 98%.
Site: Flat.
Buildings: Steel and concrete; asbestos-cement sheet siding and roof.

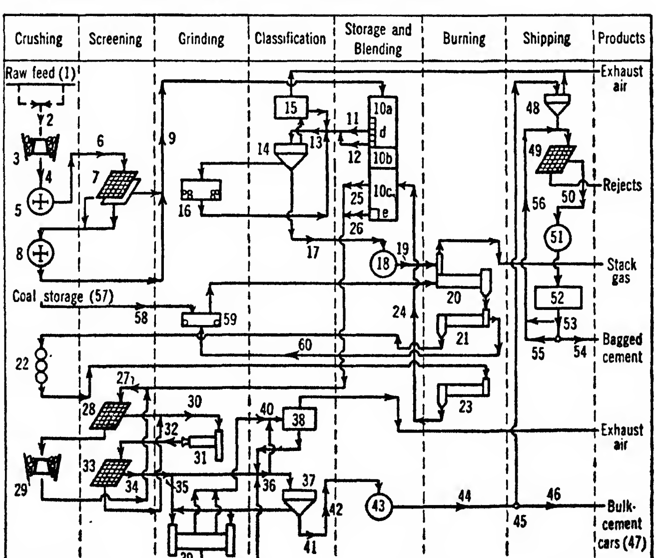

FIG. 18. UNIVERSAL ATLAS CEMENT Co., Hudson plant.

Legend for Fig. 18:

1. Shale and limestones of different grades from different parts of the same quarry. Typical analyses are given in Table 22. Shale and limestone are quarried and run through to storage separately always; more or less segregation is also practiced with the limestones.

2. 2 1/2-cyd. shovels at quarry; average 1/2 mi. quarry to crushing plant; 20-ton side-dump cars, 5 in a train, dumped by air-operated hoist. 2- to 3-ft. maximum lumps.

3. 1 @ 42-in. short-shaft gyratory crusher, 122 gyrations per min., 300-hp. motor; 0.5 to 0.7 hp-hr. per ton.

4. 1 @ 5×24-ft. apron feeder.

5. 1 hammer mill, 16-disk, 58-in. hammer circle; 700-hp. motor. Product, <1 1/2-in. or 3/4-in. 1.6 hp-hr. per ton (yearly average).

6. 1 @ 30-in.×1,200-ft. belt conveyor, 514 f.p.m.; 1 @ 30-in.×98-ft. belt conveyor with Weightometer and 2 horseshoe magnets, 1.5-sq. ft. poles.

7. 1 @ 6×12-ft. 2-deck Ty-rock screen, 1 1/4- or 1-in. Ty-rod cover on upper deck, 1- or 3/4-in. on lower.

8. 1 @ 36×50-in. hammer mill, 125-hp. motor.

9. 1 @ 30-in.×330-ft. belt conveyor with traveling tripper.

10. Flat-bottomed concrete storage bin 30 ft. (deep)×104×555 ft., served by traveling crane with grab bucket. *a*, 104×260-ft. limestone storage, about 33,000 tons live capacity; carried nearly full, particularly in winter; *b*, 104×35-ft. shale storage; *c*, 104×260-ft. clinker storage; *d*, crane-filled mill-feed surge bins; *e*, gypsum storage.

THREE PARALLEL CIRCUITS, EACH AS FOLLOWS:

11. 1 @ 26-in.×23-ft. belt conveyor, 19.2 f.p.m., with Weightometer control of bin gate for feeding limestone at a predetermined rate.

12. 1 @ 22-in.×23-ft. belt conveyor, as (11), and proportioning control, clutch-driven from (11), for shale; clutch is thrown in or out according to whether shale is desired in the raw feed to the grinding mills.

13. 1 vertical carrier-type chain-bucket elevator, 4.75-cu. ft. buckets, 24-in. pitch, 80 f.p.m.; lift 60 ft.

14. 1 @ 16-ft. air classifier, 172 r.p.m., 12-blade fan plus 22 auxiliary blades, 4,000 to 5,000 cu. ft. per min. (70° F. basis) at 450 to 750° F. 110 hp. consumed; screen analyses, % >200-m.: feed, 81; sand, 86; fines, 8 to 9.

15. 1 @ 8 1/2-ft. 200-bag dust collector.

16. 1 @ 3-ring 66-in. ball-ring mill. Feed: ±1% >1-in., @ 23% >1/2-in. Power consumed, 14.3 hp-hr. per ton of new feed to mill; 20.2 hp-hr. per ton for grinding circuit. 1,000 to 2,500% circulating load (calculated from screen tests).

STREAMS COMBINE

17. 1 @ 18-in.×65-ft. screw conveyor; 1 @ 10-in. Fuller-Kinyon pump, lift @ 90 ft., horizontal run @ 350 ft.

18. 6 @ 30 (diam.)×62 ft. blend-storage bins; 2 @ 25×62-ft. compressed-air mixing bins for the three grinding circuits.

19. 18-in. screw-conveyors; 2 @ 10-in. Fuller-Kinyon pumps; 2 @ 27 (diam.)×45-ft. steel bins; screw conveyor; elevator; surge bin; screw feeder.

CLINKERING

20. 3 @ 12×233-ft. rotary kilns; 6-in. standard fire-clay brick lining; slope 5/16 i.p.f.; adjustable speed, ±77 r.p.h.; maximum temperature of clinker at end of burning zone, 2,700° F.; exit gases, 1,600 to 1,700° F.

21. 3 @ 10×78-ft. rotary coolers, 45 r.p.h.; slope, 1 1/4 i.p.f.

22. 3 @ 12×36-in. 3-roll crushers.

23. 3 @ 6 1/2×80-ft. rotary coolers; 90 r.p.h.; slope, 7/8 i.p.f.; clinker temperature at discharge @ 160° F.

24. 3 @ 8×16-in. Salem-type bucket by 45-ft. vertical chain-bucket elevators; clinker scales; 1 @ 16-in.×90-ft. belt conveyor, 285 f.p.m.; 1 @ 24-in.×87-ft. belt conveyor, 285 f.p.m.; 1 @ 16-in.×99-ft. belt conveyor, 295 f.p.m.; 1 @ 24-in.×60-ft. belt conveyor, 295 f.p.m.; 1 @ 16-in.×216-ft. belt conveyor, 287 f.p.m.; 1 @ 24-in.×224-ft. belt conveyor, 287 f.p.m.

CLINKER GRINDING

25. 1 regulating feeder as (11).

26. 1 regulating feeder as (11).

27. 1 vertical chain-bucket elevator, 88 f.p.m., 62-ft. lift. Bucket size: 20×12×17 5/8-in., 1.9-cu. ft.

28. 1 @ 4-ft.×8-ft. Hum-mer screen, 3/8-in. aperture.

29. 1 @ 10-in. Newhouse crusher, 1/2-in. set.

30. 1 @ 24-in.×38-ft. belt conveyor, 218 f.p.m.; 1 @ 35-ton surge bin; 1 @ 8 1/2-ft. 168-bag dust collector.

31. 1 @ 10 1/2×12-ft. ball mill; 117,000 lb. @ 2-in. (renewal-size) balls; 18 r.p.m.; 700-hp. motor; liners, plate-type (steel), 2 in. thick when new.

32. 1 vertical chain-bucket elevator, 92 f.p.m., 55-ft. lift; bucket size, 30×12×17 5/8-in., 2.79-cu. ft.

33. 1 @ 4×8-ft. Hum-mer screen, 20-m.

34. 1 @ 18-in.×86-ft. screw conveyor, 62 r.p.m.

THREE PARALLEL OR SERIES CIRCUITS, EACH AS FOLLOWS:

35. 1 @ 40-ton surge bin; 1 constant-volume feeder; 1 splitter.

36. Split stream to one of two items (37): 1 @ 12-in.×20-ft. screw conveyor, 61 r.p.m.; 1 @ 62-ft. (lift) vertical chain-bucket elevator, 88 f.p.m.; bucket size, 20×12×17 5/8-in., 1.9-cu. ft.

37. 2 @ 16-ft. air classifiers in parallel.

38. 1 @ 8 1/2-ft. 216-bag suction-type dust collector; takes suction on elevator (36) and mill (39).

39. 1 @ 8×30-ft. 2-end feed, center-discharge tube mill, 160,000-lb. charge of 7/8-in. (steel) balls; 19.9 r.p.m., 700-hp. motor.

40. Suction lines.

41. 1 @ 18-in.×67-ft. screw conveyor, 62 r.p.m.

STREAMS COMBINE

42. 1 @ 8-in. Fuller-Kinyon pump, 110-ft. lift, 750- to 850-ft. run.

43. 12 @ 26 (diam.)×60-ft., 12 @ 26×100-ft., 10 @ 26×90-ft. cement-storage bins, all with interstice bins, with Fuller-Kinyon transfer system.

44. 1 @ 8-in. traveling F-K pump.

45. Valve.

46. 1 @ 120-bbl. surge bin.

47. Loaded on track scale.

Legend for Fig. 18—Continued:

SEVERAL PACKING UNITS AS FOLLOWS:

48. Air releaser.
49. 1 @ 4×5-ft. vibrating screen, 0.147-in. aperture.
50. 1 @ 120-bbl. surge bin; 1 rotary type feeder; 1 @ 12-in.×24-ft. screw conveyor with excess release to (56).
51. 1 @ 10-bbl. packing hopper.
52. 1 @ 4-valve Modern valve-type packing machine.
53. 1 @ 26 1/2-in.×21-ft. wire-mesh conveyor, 115 f.p.m.
54. Bags.
55. Dust.
56. 1 @ 16×8-in. Salem-type bucket, 50-ft. lift elevator, 275 f.p.m.

COAL HANDLING

57. Western Pennsylvania bituminous slack.
58. 1 @ 24-in.×300-ft. belt conveyor, 400 f.p.m.; 1 @ 24-in.×265-ft. belt conveyor, 400 f.p.m.; 1 @ 24-in.×110-ft. belt conveyor, 405 f.p.m.; 1 @ 24-in.×203-ft. belt conveyor, 166 f.p.m., with magnetic head pulley and Merrick Weightometer; 1 @ 20-in.×75-ft. screw conveyor; 1 @ 11 (diam.)×19-ft. surge bin.
59. 3 @ 1-stage, 44-in. ball-ring unit coal pulverizers in parallel; product 18% >200-m. Power consumption, 16 hp-hr. per ton.
60. 3 @ 40-in. blast fans. Air temperature, 300° F.

Table 22. Typical analyses of shale and limestone at Hudson plant

Stone	Percentages				Ratios	
	SiO_2	Al_2O_3	Fe_2O_3	$CaCO_3$	A/F	S/R
Shale	63.7	15.9	5.6	4.7	2.84	2.96
Port Ewan limestone	16.9	2.7	1.5	76.6	1.80	4.02
Becraft limestone	6.1	1.9	2.3	87.3	0.83	1.45
New Scotland limestone	50.2	7.6	4.0	34.0	1.90	4.32

Summary: Three-stage open-circuit crushing in gyratory and hammer mills from <42-in. to <3/4-in. One-stage dry raw grinding to 8% >200-m. in ball-bearing mill in closed-circuit with an air classifier. Clinker crushed to <3/8-in. in gyratory, and ground in two stages, the first a ball mill in closed-circuit with a screen, the second a tube mill in closed-circuit with an air classifier.

Compañia Argentina de Cemento Portland. Fig. 19 (*Q* compiled by R. C. Ried).

Location: Parana, Argentina, S. A.
Rock: A mixture of shell limestone, clay, and marl too low in lime and high in silica for cement manufacture without adjustment. Silica grains are coarse. See Table 23.
Capacity: 1,100 t.p.d. raw rock.

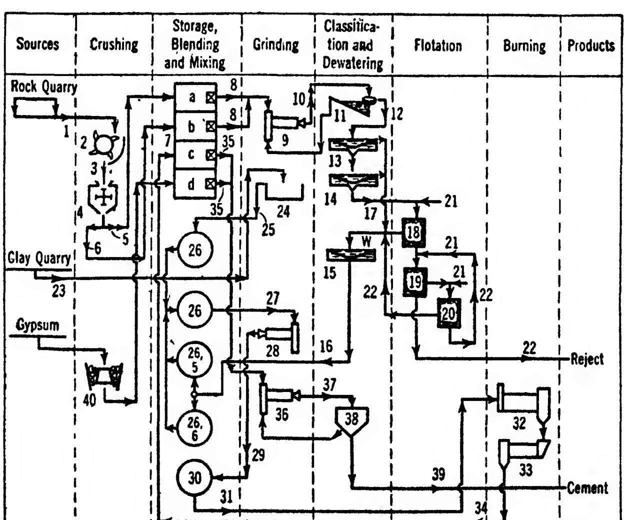

FIG. 19. COMPAÑIA ARGENTINA DE CEMENTO PORTLAND.

Legend for Fig. 19:

1. Overburden removed by #616 Bucyrus-Monighan walking electric dragline, 5-cyd. bucket, 200-ft. boom, 300-hp. motor; Diesel crawler-type tractor; 15-ton crawler-type wagon. Stone loaded by #85-B Bucyrus-Erie crawler-type electric dragline, 2 1/2-cyd. bucket, 85-ft. boom, 150-hp. motor; 2 @ 26-ton oil-fired steam locomotives; 6 air-operated 10-cyd. steel dump cars and 10 @ 10-cyd. steel side-dump cars; 1 electric-driven car dump with solenoid brake.

2. 1 @ 36×60-in. single-roll crusher, 4-in. set, 40 r.p.m., 200-hp. slip-ring motor and V-belt drive; 200 t.p.h. capacity.

3. 1 @ 48-in. pan conveyor, 10-hp. squirrel-cage motor with speed reducer.

4. 1 @ 50×50-in. hammer mill, 700 r.p.m., 1-in. grate aperture, 250-hp. slip-ring motor direct-connected; capacity, 200 t.p.h.

5. Low-lime rock. See Table 23.

6. High-lime rock. See Table 23.

7. 1 @ 75×225-ft. reinforced-concrete storage bin; capacity: stone, 14,000 tons; gypsum, 4,000 tons; clinker, 38,000 bbl.; 7 1/2-ton traveling crane, 75-ft. span, 3-cyd. clamshell bucket with 50-hp. motor; crane travel, 350 f.p.m., 30-hp. motor; crane trolley, 200 f.p.m., 7 1/2-hp. motor; hoist, 150 f.p.m., 50-hp. motor. *a*, low-lime rock; *b*, high-lime rock; *c*, clinker; *d*, gypsum.

8. 2 @ 60-ton reinforced-concrete bins; 2 @ 6 1/2-ft. table feeders (see Challenge feeders, Sec. 18) with 7 1/2-hp. motors with speed reducers.

9. 1 @ 9×11 1/2-ft. ball mill, 18.4 r.p.m., 65,000 lb. @ 3 1/2-in. balls, 450-hp. synchronous motor with speed reducer. See Table 23.

10. 1 @ 39×78-in. center-discharge bucket elevator, 15-hp. motor.

11. 1 @ 20 (diam.) ×16×33-ft. bowl-rake classifier, 1 to 3 r.p.m., 12 s.p.m.; 5- and 10-hp. motors. See Table 23.

12. 1 @ 5-in. 850-g.p.m. centrifugal pump, 50-hp. motor; 2 @ 23 (diam.) ×23-ft. reinforced-concrete tanks with Turbomixers, 20-hp. motors; 1 @ 5-in. 1,000-g.p.m. centrifugal pump; 1 @ 5 (diam.) ×5-ft. steel surge tank with Turbomixer, 2-hp. motor.

13. 1 @ 45-ft. (diam.) ×18-in. reinforced-concrete Hydroseparator, 0.75 r.p.m., 5-hp. motor. See Table 23.

14. 1 as (13). See Table 23.

15. 1 @ 180 (diam.) ×8-ft. Torq-type thickener, 0.044 r.p.m., 3-hp. motor; underflow, 62% solids; return of overflow to mill circuit reduces consumption of flotation reagent. See Table 23.

16. 1 @ 4-in. 200-g.p.m. centrifugal pump, 40-hp. motor.

17. 1 @ 10 (diam.) ×15-ft. reinforced-concrete surge tank with Turbomixer, 7 1/2-hp. motor; 1 @ 4-in. 800-g.p.m. centrifugal pump, 15-hp. motor; 1 @ 5 (diam.) ×5-ft. steel tank with Turbomixer, 2-hp. motor.

18. 4 @ 56-in. Fagergren cells in series. See Table 23.

19. 4 as (18). See Table 23.

20. 2 as (18). See Table 23.

21. Partly saponified AC 708 (Talloel) added by individual bucket-type feeders to each cell. Degree of saponification varied to change relative frothing and collecting properties as desired. Froth is watery and breaks down with water sprays in thickener.

22. 4 @ 4-in., 300- to 500-g.p.m. centrifugal pumps, 7 1/2- to 15-hp. motors, on streams in flotation house.

23. Loaded by dragline; transport as for rock (1).

24. Wash mill, 11 r.p.m., 30-hp. motor, 15 t.p.h.

25. 1 @ 4-in. 400-g.p.m. centrifugal pump, 25-hp. motor.

26. 6 @ 23 (diam.) ×23-ft. reinforced-concrete blending tanks with mechanical agitation (2 @ 20-hp. motors) and air agitation (1 rotary compressor, 254 cu. ft. per min. @ 50-lb. pressure, 50-hp. motor); 1 @ 6-in. 900-g.p.m. centrifugal pump, 60-hp. motor.

27. 1 @ 28×60-in. center-discharge bucket elevator, 10-hp. motor.

28. 1 @ 7×26-ft. tube mill, 19.4 r.p.m.; 450-hp. synchronous motor.

29. 1 as (27).

30. 2 @ 56 (diam.) ×25-ft. reinforced-concrete storage tanks, with radial and central agitators, 20- and 7 1/2-hp. motors respectively; 1 @ 6-in. 900-g.p.m. centrifugal pump, 60-hp. motor.

31. 1 @ 69×28-in. center-discharge elevator, 10-hp. motor; 1 bucket-type slurry feeder, 1-hp. motor.

32. 1 @ 11- and 10×400-ft. rotary kiln with chain section; 140-hp. motor; draft fan, 100-hp. motor; reinforced-concrete stack, 9 (diam.) × 110 ft.; 0.445 to 0.9 r.p.m., 4% slope, 42% moisture in feed, oil fuel, 1,100,000 B.t.u. per bbl. of clinker.

33. 1 @ 9×120-ft. rotary cooler, 75-hp. motor; 2.9 r.p.m., slope, 3%; steel lifters.

34. 1 @ 16-in.×124-ft. shaking conveyor, 15-hp. motor; 1 @ 49×26-in. center-discharge bucket elevator.

35. Constant-weight feeders.

36. 1 @ 8×40-ft. tube mill, 18.8 r.p.m.; compartment 1, 42,000 lb. @ 2- to 3 1/2-in. balls; compartment 2, 32,000 lb. @ 1 1/4- to 2-in. balls; compartment 3, 43,000 lb. @ 3/4- and 7/8-in.; compartment 4, 42,000 lb. @ 1/2- to 3/4-in.; 1,050-hp. synchronous motor.

37. 1 @ 69×32-in. center-discharge bucket elevator, 20-hp. motor.

38. 1 air separator, 35-hp. motor; fan, 125-hp. motor; dust filter, 2-hp. motor; filter fan, 10-hp. motor.

39. Cement pump; rotary air compressor, 60 cu. ft. per min., 60-lb. pressure, 125-hp. motor; 8 reinforced-concrete silos, 124,000-bbl. capacity; 2 @ 7-in. 400-bbl.-per hr. portable cement pumps with 100-hp. motors and 2 @ 722-cu. ft. per min. (40-lb.) rotary compressors with 100-hp. synchronous motors; 4 @ 4-spout automatic bag packers, 25-hp. motors; 2 @ 30-in. reversible belt conveyors; 1 @ 42-in. inclined belt conveyor; 1 @ 42-in.×140-ft. belt conveyor (15-hp. motor).

40. Gyratory crusher.

Summary. Two-stage crushing from run-of-quarry to <3/4-in.; two-stage wet grinding with intervening rejection of coarse silica by classification and lime flotation. Rotary cooling. One-stage closed-circuit clinker grinding.

Table 23. Quantities and analyses for Parana plant

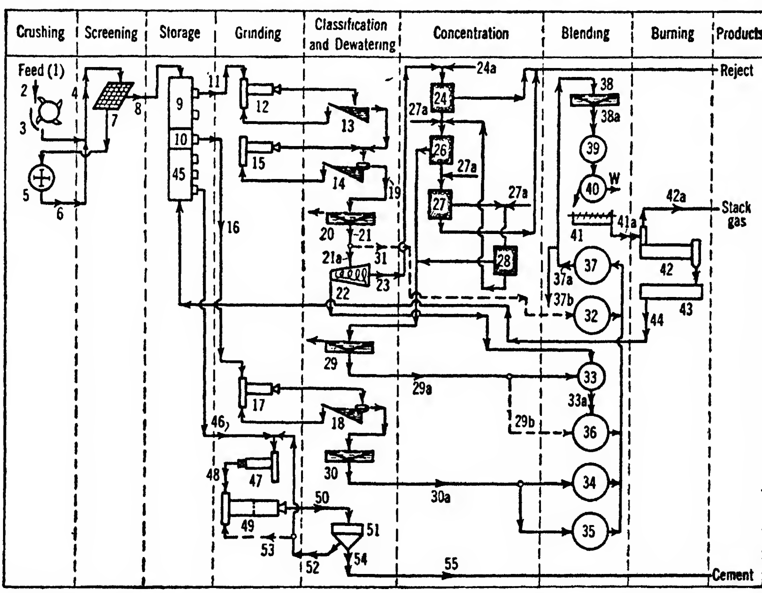
a Flotation feed. *b* Combined rejects. *c* After thickening; thickener feed, 13% solids.



Legend for Fig. 20:

1. For analysis see Table 24.

2. Quarry, 2 1/2-cyd. shovels, max. size loaded about 3- to 4-ft. lumps. Average distance quarry to crusher, 1/2 mi.; haulage by 20-ton side dump cars, 8 cars per train. (From a lower quarry level gasoline tractors with 10 cyd. semi-trailers will be used, assisted up a 750-ft. 10% ramp by electric hoist (*7 # 5 MT, TP 1619*).) Feeder: 60-in.× 18 1/3-ft., apron-type.

3. 1 @ 36×60-in. Fairmount single-roll crusher, 6-in. set, 48 r.p.m., 250-hp. motor; capacity, 400 t.p.h.

4. 1 @ 36-in.×300-ft. inclined (+18°) belt conveyor to screen; 475 f.p.m.

5. 1 @ 15-disk hammer mill, 48-in. hammer circle, 720 r.p.m., 600-hp. motor, grates set for 3/4-in. product; capacity, 425 t.p.h.

6. 1 @ 30-in.×111-ft. inclined belt conveyor, 450 f.p.m.

7. 2 @ 5×12-ft. Ty-rock screens in parallel, 3/4- to 1 1/4-in. aperture, according to moisture content.

8. 1 @ 30-in.×500-ft. inclined belt conveyor, 27-ft. lift; 1 @ 30-in.×300-ft. distributing conveyor with traveling tripper.

Fig. 20. Universal Atlas Cement Co., Northampton wet-process plant.

Legend for Fig. 20—Continued:

9. Cement-rock storage (see Fig. 21).
10. Sand and iron storages (see Fig. 21).

TWO PARALLEL ROCK CIRCUITS EACH AS FOLLOWS:

11. 1 feed hopper crane-filled from (9); 1 @ 24-in. Feedoweight.
12. 1 @ 9 1/2×8 2/3-ft. ball mill, 19 r.p.m.; 60,000 lbs. @ 2-, 2 1/2-, and 3-in. forged-steel balls; Lorain-type rolled-steel liners, 2 1/2 in. thick; 350-hp. direct-connected motor, 180 r.p.m.
13. 1 @ 8×25 1/2-ft. heavy-duty duplex rake classifier; slope, 2 1/2 in. per ft.; 25 s.p.m.
14. 1 @ 27(diam.)×16×40 1/2-ft. quadruplex bowl-rake classifier; slope, 2 in. per ft.; rake speed, 10 to 12 s.p.m.; bowl rake, 1/2 to 11/2 r.p.m. variable; overflow, 13 to 15% solids.
15. 1 @ 9 1/2×8 2/3-ft. ball mill, 18 1/2 r.p.m.; 60,000 lbs. @ 7/8-, 1-, and 1 1/4-in. forged-steel balls; Lorain-type rolled-steel liners, 2 1/2 in. thick; 350-hp. direct-connected motor, 180 r.p.m.

SAND AND IRON CIRCUIT

16. 1 @ 24-in. Feedoweight.
17. 1 @ 8×7 2/3-ft. ball mill, 20 r.p.m.; 35,000 lb. @ 1 1/4-, 1 1/2-, 2-, and 2 1/2-in. forged-steel balls; Lorain-type rolled-steel liners, 2 1/2 in. thick; 200-hp. direct-connected motor, 180 r.p.m.
18. 1 @ 10(diam.)×6×31 1/2-ft. duplex bowl-rake classifier; slope, 2 in. per ft.; rake speed, 12 to 15 s.p.m.; bowl rakes, 0.8 to 2.4 r.p.m. variable.

TWO RAW-ROCK LINES COMBINE

19. 1 @ 10-in. centrifugal pump.
20. 1 @ 200×10-ft. traction-type thickener, 60 m.p.r.; overflow returns to raw mill. See Table 24.
21. 1 (of 2) 5-in. centrifugal pump.
21a. 1 Turbomixer, 61,500-gal. capacity (24 (diam.)×20-ft.); 1 @ 6-in. centrifugal pump; 1 constant-level surge tank (overflow return to Turbomixer).
22. 2 @ 54×70-in. centrifugal classifiers in parallel; 125-hp. motors with magnetic clutch, permitting variation in centrifugal speed from 350 to 600 r.p.m. See Table 24.
23. 1 @ 61,500-gal. Turbomixer; 1 @ 8-in. centrifugal pump; 1 constant-level surge tank (overflow return to Turbomixer).
24. 4 @ 3-cell 60-in. square-type Fagergren flotation machines in parallel to skim out carbon-bearing overflow; feed, 17% solids, 16 to 20 t.p.h. See Table 24.
24a. Reagents: light-gravity fuel oil (medium-furnace and DuPont B-23 frother.
25. Reject settling basin and 6-in. centrifugal pump to return water overflow to Turbomixers. See Table 24.
26. 4 @ 5-cell 66-in. square-type Fagergren flotation machines in parallel (rougher cells). See Table 24.
27. 4 @ 6-cell 66-in. square-type Fagergren flotation machines in parallel (scavenger cells). See Table 24.
27a. Goulac added to first cell to disperse remaining carbonaceous material. Low-titre oleic acid and saponified modified tall oil (AC S-196) stage-added, the oleic to each cell in items (26) and (27) and the first three cells of (28), the S-196 to each cell in items (26) and (27). B-23 is stage-added to the first few cells of (26) only.
28. 4 @ 4-cell 66-in. square-type Fagergren flotation machines in parallel (cleaner cells). See Table 24.
29. 1 @ 200-ft. traction-type thickener, 60 m.p.r.; overflow to Turbomixers.
29a. 1 (of 2) 4-in. centrifugal pump.
29b. Alternative line.
30. 2 @ 50-ft. thickeners in parallel, one for sand and one for iron; items (16), (17), (18) are used alternatively for one or the other feed.
30a. 1 @ 4-in. centrifugal pump.
31. Alternative line for feeding raw rock direct to blend tanks.
32. 1 (any of 6) @ 30(diam.)×22-ft. blending tanks for cement rock.
33. 1 mixing tank.
33a. 1 @ 6-in. centrifugal pump.
34. 1 as (32) for iron.
35. 1 as (32) for sand. See Table 24.
36. 1 (any of 6) as (32) for cake and/or concentrate. See Table 24.
37. 1 (any of 6) as (32) for blended mix.
37a. Double sump and 3 @ 8-in. centrifugal pumps.
37b. Alternative recirculating lines to any of the 6 blending tanks (37).
38. 2 @ 80-ft. storage tanks in parallel, 4,000 short tons capacity each. See Table 24.
38a. 4 @ 5-in. centrifugal pumps.

FOUR PARALLEL CLINKERING UNITS EACH AS FOLLOWS:

39. 2 @ 24(diam.)×20-ft. kiln-feed tanks in parallel; 1 @ 3-in. centrifugal pump.
40. 2 @ 9-disk 8-ft.10-in. filters, water overflow to Turbomixers; cake, 23% moisture.
41. 1 @ 16 1/2-ft. pug mill.
41a. 1 reciprocating-pump filter-cake feeder.
42. 1 rotary kiln (3 @ 10 1/2×250-ft., 1 @ 9×248-ft.); 125-hp. motors; powdered coal.
42a. 1 (of 3) waste-heat boiler; rating, 28,000 lb steam per hr.
43. 1 clinker cooler (3 @ 4 1/2×40-ft. vibrating, 1 inclined-grate, all air-quench type, sending secondary air to kiln).
44. 1 @ 20-in.×25-ft. vertical continuous-bucket elevator; 1 @ 24-in.×8-ft. belt conveyor with Weightometer.
45. Clinker storage, see Fig. 21.

THREE PARALLEL CLINKER-GRINDING UNITS EACH AS FOLLOWS:

46. 1 @ 24-in.×12-ft. double Feedoweight conveyor for clinker and gypsum; 1 @ 20-in.×27-ft. vertical continuous-bucket elevator, 240 f.p.m.
47. 1 @ 9 1/2×8 2/3-ft. ball mill, 19 r.p.m.; charge, 60,000 lb. @ 1 1/4- to 3-in. graded forged-steel balls; liner, Lorain-type, rolled-steel, 2 1/2-in. thick; motor, 400-hp., 180 r.p.m.
48. 1 @ 16-in.×34-ft. vertical continuous-bucket elevator, 293 f.p.m.
49. 1 @ 8×30-ft. 2-compartment tube mill, 20.5 r.p.m.; charge: compartment 1: 80,000 lb. @ 1 1/4- to 7/8-in. graded forged-steel balls; compartment 2: 80,000 lb. @ 3/4-in. forged-steel balls; liners, Lorain-type, rolled-steel, 1 1/2 in. thick; segmental-steel discharge grate, 2 in. thick, 3/8-in. slotted apertures; motor, 800-hp., 180 r.p.m.
50. 1 @ 16-in.×12-ft. spiral conveyor, 60 r.p.m.; 1 @ 30-in.×70-ft. lift continuous-bucket elevator, 102 f.p.m.; proportioning splitter gate; 2 @ 16-in.×12-ft. spiral conveyors.

Legend for Fig. 20—Continued:

STREAMS CONVERGE

51. 2 @ 16-ft. air separators in parallel.
52. 1 @ 16-in.×72-ft. spiral conveyor, 60 r.p.m.
53. Alternative spout.
54. 2 @ 16-in.×12-ft. spiral conveyors.
55. 1 @ 18-in.×12-ft. spiral conveyor; 1 @ 8-in. Fuller-Kinyon pump to storage, packing and loading. See Fig. 21.

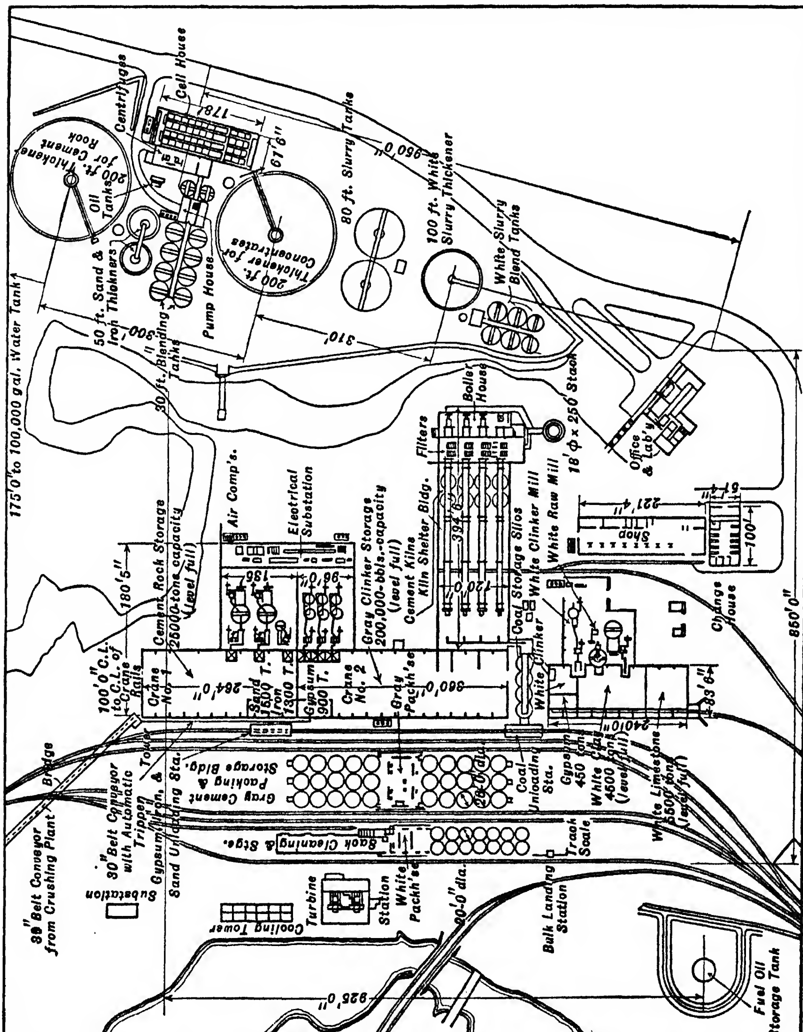


FIG. 21. Plan of Northampton plant (Fig. 20).

Summary. Two-stage crushing from run-of-quarry to <1 $1/4$-in. or $3/4$-in. by single-roll and hammer mill, with circuit closed on the second stage; two-stage wet ball-mill grinding to 96% <200-m., both circuits closed, the first by a rake, the second by a bowl-rake classifier. About 40% of ground raw rock taken directly to raw mix (for standard cement); about half of the remainder taken out by centrifuge; and not subjected to further treatment prior to blending; remainder, comprising about 30% by weight of raw rock, with a desired size of 100% <30-μ, is floated to produce a high-lime (86 to 87%) concentrate (see Table 25). Blending is effected at about 65% solids, and the blended product filtered to 21% moisture and pugged before burning. Clinker is ground in two stages, the first a substantially open-circuit ball mill, the second a tube mill with circuit closed by air classifier.

Permanente Corporation. Fig. 22 (*148 A 374; 43 # 12 RP 36; 33 # 6 PQ 27*).
Location: Near San Jose, Calif.
Rock: $CaCO_3$, average 85%; SiO_2, variable and high in certain sections of quarry. See Tables 25 and 26.

Table 25. Run-of-quarry rock at Permanente

Size, in.	Weight, %	Analyses, %					
		SiO_2	Al_2O_3	Fe	CaO	MgO	Ignition loss
6	12.5	1.6	0.7	0.3	54.1	0.4	42.7
5	4.8	4.3	0.6	0.3	52.7	0.2	41.8

2	8.0	5.6	0.8	0.3	51.8	0.2	41.4
1 1/2	8.9	5.3	0.9	0.3	52.5	0.2	41.3
1/2	18.7	8.2	0.9	0.4	50.5	0.3	40.2
<1/2	16.9	24.1	3.6	1.4	38.9	0.5	31.9

Capacity (Feb. 1941): 12,000 bbl. per day; 3,130 t.p.d. of raw limestone, 620 t.p.d. clay, about 100 t.p.d. gypsum.
Products: Cements: Low-heat, normal, moderate-heat, moderate sulphate-resistant, high-early-strength, oil-well, modified oil-well, plastic. Shasta Dam specification cement, as follows, was the kind being made at the time of the tests tabulated herein: Ignition loss, 2.25%; insol., 0.75%; SO_3, 2.25%; MgO, 5%; uncombined CaO, 1.25%; Fe_2O_3/Al_2O_3, 1.5; C_3S, 35% max.; C_2S, between 40 and 65%; C_3A, 7% max.; C_4AF, 20% max. Average specific surface on bin sampling, 1,800 sq. cm. per gm.; no individual sample less than 1,600 sq. cm. per gm. 7-day strength, 750 lb. per sq. in.; 28-day, 2,000 lb. Sugar rock, 600 tons per 8 hr. Lime, 100 t.p.d., from breakage of sugar rock. Crushed stone from sugar rock or cement rock, 200 t.p.h. capacity.

Table 26. Clays at Permanente

Item	No. 1	No. 2	No. 3	No. 4
SiO_2.....	47.2	66.2	46.7	46.2
Fe_2O_3...	13.8	5.4	11.8	11.2
Al_2O_3....	16.1	15.1	16.2	12.9

Legend for Fig. 22:

1. 5-cyd. shovel.

2. Hopper; vibrating feeder; 1 @ 36-in.×100-ft. pendulum conveyor (down-hill flow); 1 @ 1,000-ft. (max. extension) conveyor; 1 field conveyor. 30-cyd. Le Tourneau buggies alternative to the conveyors.

3. 1 @ 5,000-ton stockpile.

4. 1 @ 42-in. pan feeder; 1 @ 42-in.×400-ft. belt conveyor with Weightometer.

5. 1 @ 5×10-ft. Ty-rock screen, 6-in. apertures.

6. 1 @ 24×36-in. Farrell-Bacon jaw crusher, 6-in. open setting; 100-hp. motor.

7. 1 @ 36-in.×1,630-ft. belt conveyor, 130-ft. fall; 1 @ 36-in.×2,225-ft. belt conveyor, 232-ft. fall; 1 @ 36-in.×1,300-ft. belt conveyor, 237-ft. fall. Speeds, 500 f.p.m.; 8-ply, 42-oz. belt, 54-in. pulleys. Control of each conveyor is by a 200-hp. synchronous geared regenerative motor; at full load 260 kw. is generated.

8. 1 @ 5×10-ft. 2-deck Ty-rock screen, 6- and 3-in. apertures.

9. 6~3-in. sugar rock (for sugar industry); 100,000-ton stockpile.

10. 1 @ 36-in.×400-ft. boom conveyor; several-hundred-foot drop at discharge.

11. 550,000-ton stockpile.

12. 1 @ 36-in. tunnel conveyor with vibrating feeders.

13. 1 @ 5×10-ft. 2-deck Ty-rock screen and 1 @ 4×10-ft. Seco screen in parallel, 1 1/2- and 3/4- or 1/2-in. apertures.

14. 1 @ No. 49 Kennedy-Van Saun low-head gyratory crusher, 125-hp. motor; and 1 @ 4-ft. short-head cone, 150-hp. motor; in parallel.

15. 5,000-ton stockpile.

16. Alternative routing.

17. "Clay" is sandstone and andesite, tough and resistant to grinding. Trucks; hopper near plant; pan feeder; belt conveyor.

18. 1 @ 4×5-ft. vibrating screen, 3/8-in. aperture.

19. 1 @ No. 3 A-C hammer mill (Pulverator); 50-hp. motor.

20. Vibrating feeders; 1 @ 24-in. belt conveyor in tunnel; 2 @ 400-ton circular hopper-bottomed steel bins; Merrick Feed-O-Weights. Feed tonnage ranges from 90 t.p.h. when grinding to 75% <200-m. to 150 t.p.h. when grinding to 50% <200-m.; and at any given *mog* falls approximately 2% for each 1% reduction in $CaCO_3$ content. See table 27.

21. 1 @ 9 1/2×10-ft. Traylor and 1 @ 9×10 1/2-ft. Smidth ball mills (both inside dimen-

FIG. 22. PERMANENTE CORPORATION.

Legend for Fig. 22—Continued:

sions); 19 r.p.m., 3/4-in. grate apertures; pulp 75 to 80% solids; 500-hp. motors. Original charge, each mill: 39,500 lb. @ 4-in. balls, 31,000 lb. @ 3-in., 6,500 lb. @ 2 1/2-in.; make-up is half-and-half 4-in. and 3-in. Consumption 0.75 lb. per ton. All mills dumped at 4-mo. intervals and recharged on their original ration.

22. 2 @ 8-ft. Dorrco sand wheels, attached to mill-discharge trunnions.

23. 2 @ 12×31 1/2-ft. quadruplex rake classifiers, 26 s.p.m.; overflow, 16 to 30% solids; 30-hp. motor. See Table 27.

24. 2 @ 28(diam.)×16×42-ft. bowl-rake classifiers, with 5-hp. and 25-hp. variable-speed motors; normal speeds, 9 s.p.m. and 1.5 r.p.m. for rakes and bowl respectively for 95 to 96% <200-m. overflow at about 13% solids; sands about 78% solids. See Table 27.

25. 1 @ 9 1/2×10-ft. A-C ball mill, 500-hp. motor, and 1 @ 9 1/2×10-ft. Traylor ball mill, 500-hp. motor, both with 3/8-in. grates, 19 r.p.m., and 77,000-lb. ball charges as follows: 3,000 lb. @ 2-in., 14,000 lb. @ 1 1/2-in., 20,000 lb. each @ 1 1/4-, 1-, and 3/4-in. with make-up at 2 1/2- and 2-in. See (21). Consumption, 0.75 lb. per ton. Capacity of circuit grinding to 96% <200-m. is 150 t.p.d. with feed containing 90% $CaCO_3$ and 2% >48-m. See Table 27.

26. 2 @ 11-ft. Dorrco sand wheels, attached to mill-discharge trunnions.

27. 1 @ 7×26-ft. 2-compartment ball-tube mill, 500-hp. motor; discharge, 52% <200-m. Ball charges: first compartment, 8,000 lb. @ 5-in., 6,000 each @ 4-, 3 1/2- and 2 1/2-in.; second compartment, 16,000 lb. @ 2 1/2-in., 12,000 @ 2-in., 22,000 @ 1 1/2-in.; consumption 2 to 3 times that of limestone mills.

28. 3 @ 4×6-ft. Hum-mer screens, 28-m. aperture.

29. 1 @ 7×26-ft. Smidth ball mill, 500-hp. motor; discharge 55% solids, 71% <200-m. Ball charge: 9,000 lb. @ 2-in., 7,000 @ 1 1/2, 6,000 @ 1-in., 19,000 @ 7/8-in., 39,000 @ 3/4-in.

30. Storage. Pulp accumulated and then recirculated until reduced to 85% <200-m. More than two-thirds of the power consumption in clay grinding is in this secondary circuit.

31. Alternative flow.

32. 2 @ 45-ft. hydro-bowl classifiers; overflow, 5% solids, 97% <325-m., about 20% of dry feed; underflow, 30% solids.

33. 1 @ 23×23-ft. Turbomixer; water added to make outflow 25% solids.

34. Constant-head tank; outflow controlled by Massco-Grigsby rubber pinch valves.

35. 2 @ 3-cell 66-in. Fagergren machines in parallel; @ 100 t.p.h. dry solid. Partly saponified Talloel fed to each cell of (35, 36, 37) at rate (total) of 0.8 lb. per ton; no other reagent used.

36. As (35).

37. 2 @ 2-cell 66-in. Fahrenwald units in parallel. See Table 28.

38. Tailing pond, water reclaimed.

39. 2 @ 150×10-ft. thickeners with pickets; each thickener with 2 @ 4-in. Hydroseal pumps for recirculating (and spreading) thickened slurry. At 7,000 bbl. per day and 65% <200-m. in feed, underflow was 68% solids; at 95% <200-m., it was 66% solids; at 12,000 bbl. per day and 95% <200-m. it was 62% solids at pH 8.2; at pH 9.5 solids in underflow fall to 58 or 59%, and required area is increased about 30%.

Table 28. Analyses of flotation-plant products at Permanente (percentages)

Item	Hydro-bowl		Flotation		
	Feed	Overflow	Feed	Concentrate	Tailing
SiO_2...	12.0	5.9	15.6	3.2	92.3
Al_2O_3..	1.1	0.8	0.8	0.5	1.8
Fe_2O_3..	1.0	0.3	0.3	0.3	0.4
CaO...	48.0	51.8	47.0	53.9	3.8
MgO...	0.1	0	0.1	0.1	0.1

40. 2 @ 20(diam.)×40-ft. steel storage tanks, each for "clay" of a different composition.

41. 1 of 5 as (40), filled about 3/4, agitated by air. Carbonate content determined and calculated amount of clay added from (40). Agitated at least 30 min. and sampled. Correction to desired composition.

42. 1 of 2 @ 80(diam.)×20-ft. tanks with mixing mechanism similar to thickener arms driven at 0.2 to 0.6 r.p.m. by a 25-hp. 4-speed motor (5 to 15 hp. consumed); 12 air nozzles with porous-plate discharge distributed on arms for air agitation; also recirculation by a 3-in. pump from a center discharge to quarter points on the periphery. Discharge to kiln is from the bottom near the periphery via two outlets through Fuller automatic valves on a common line and thence through a Massco-Grigsby pinch valve to a sump having liquid-level control on the Fuller valves.

43. 1 @ 12×450-ft. Traylor kiln; 72-in. Ferris-wheel feeder. Pendent chains, 8 1/2 ft. long, 130-ft. section. Combustion air drawn through cooler (44) and thence through 2 @ 7-ft. Western Precipitation Co. Polyclones to remove the bulk of clinker dust, which is sent to clinker storage. No. 54 Buffalo fan with 150-hp. motor. Lining, see (45). 200-hp. motor; feeder motor synchronized with drive motor with adjustable speed ratio. Natural gas (1,100 B.t.u.) fuel, with standby oil burner. Kiln-control panels carry recording instruments for temperatures of exit gas and rotary-cooler gas; r.p.h. and total revolutions of kiln; CO and CO_2 in exit gas; voltage and amperage of kiln motors; fuel-gas consumption; indicating draft gage.

44. 1 @ 11 1/2×120-ft. rotary cooler, lined 40 ft. with brick.

45. 2 @ 12×11×12×464-ft. Smidth kilns with 90-ft. draped-chain sections; rated at 3,500 bbl. per day each. 10 @ 5×30-ft. Unax coolers, lined 5 ft. Kilns fed by rotary scoop. Linings all kilns: 200 ft. @ 9-in. magnesite brick, balance high alumina- and firebrick; asbestos block behind all brick. 200-hp. motors; feeder motors synchronized with drive motors on adjustable speed ratios.

45a. Grizzlies in chutes feeding crushers.

46. 2 @ 4-ft. Traylor TY reduction gyratories, one a spare; 3/8-in. set; circulating lubricating oil water-cooled.

47. Belt conveyor with movable tripper to and over (48); 2 lateral conveyors from tripper, 18 ft. long.

48. Clinker storage, 100×340-ft., 5-compartment, V-bottom to a conveyor tunnel; 160,000 bbl. capacity.

49. Tunnel conveyor fed by 2 portable Feed-O-Weights and one vibrating feeder.

50. Transfer conveyor.

51. By-pass conveyor.

Legend for Fig. 22—Continued:

52. 4 @ 1,350-bbl. clinker feed bins.

53. 2 gypsum bins.

54. 6 Feed-O-Weights.

55. 4 screw conveyors.

56. 1 @ 9 1/2×10-ft. Traylor ball mill, 61,000 lb. <4-in. balls.

57. 1 @ 8×40-ft. 2-compartment ball mill; 1,000-hp. synchronous motor; 63,000 lb. 1- and 7/8-in. steel balls in first compartment; 101,000 lb. <5/8-in. steel balls in second compartment. TDA used as a grinding aid.

58. 1 @ 8-in. Fuller-Kinyon pump.

59. 2 @ 16-ft. Raymond Double-whizzer air classifiers.

60. Alternatives, whole or partial.

61. Elevator.

62. 1 @ 9 1/2×10 1/2-ft. A-C ball mill, 77,000 lb. <4-in. steel balls.

63. As (61).

64. 1 @ 2-ended 8×40-ft. ball mill, separate center discharges; 1,000-hp. synchronous motor; 135,000 lb. Concavex in each compartment, <1 1/4- and <5/8-in. respectively in 1 and 2. TDA used as a grinding aid.

65. 2 bucket elevators.

66. 1 as (59).

67. 1 as (59).

68. 2 @ 8×36-ft. Unidan 3-compartment ball mills, 135,000 lb. <3 1/2-in. balls and Cylpebs each; 1 @ 1,000-hp. synchronous motor each. TDA used as a grinding aid.

69. 2 @ No. 250 Smidth multistage air classifiers, with 40-hp. variable-speed motors.

70. 2 cyclones; 2 fans with 125-hp. motors.

71. Separately or as blended in a screw-conveyor system.

72. 3 Fuller-Kinyon pumps, with manually operated diversion at (73).

73. 27 @ 30×90-ft. silos in 3 rows of 9, with interstice bins; combined capacity, 500,000 bbl. cement (1 silo and 1 interstice bin for gypsum); 3 @ 8-in. portable F-K pumps under bins to pack house, car-loading bin, or for circulation. Truck loading or direct car loading through rotary valves from the outside silos. Bulk car loading, 15 min. per car.

74. 1 of stock-house F-K pumps.

Summary. Two-stage crushing in jaw crusher and closed-circuit reduction gyratory to <1/2- to 3/4-in. Two-stage wet grinding in ball and tube mills (both circuits closed) to 94% <200-m. Correction of kiln feed by flotation.

Valley Forge Cement Co. Fig. 23. (Data compiled by R. C. Ried, Asst. Supt.).

Location: West Conshohocken, Pa.
Capacity: 1,330 t.p.d.
Rock: See item 9, Table 29.
Fuel: 98 lb. of 13,800-B.t.u. coal per bbl.
Power: 28.9 hp-hr. per bbl.

Legend for Fig. 23:

1. Inclined hoist from quarry in 10-ton side-dump cars; thence in trains of 4 quarry cars 1,800 ft. by 10-ton Vulcan locomotive, standard gage; 1 @ 5×11 3/4-ft. traveling-bar grizzly with push-button control.

2. 1 @ 48×60-in. Traylor jaw crusher, 6-in. set, 150-hp. motor.

3. Undersize of grizzly feeder.

4. 1 @ 36-in.×28-ft. pan conveyor.

5. 1 @ #9 Williams hammer mill, 24 (hammer circle)×32-in., 875 r.p.m., 2-in. grate setting, 350-hp. motor direct-connected. Product <3/4-in.

6. 1 @ 24×91-ft. belt conveyor.

7. 1 @ 78×154-ft. reinforced-concrete storage bin, *a* = high-lime; *b* = low-lime, silica, iron; *c* = clinker; *d* = gypsum. 1 @ 8-ton crane, 80-ft. span, 2 1/4-cyd. bucket, 15-hp. trolley motor, 2 @ 50-hp. hoist motors, 1 @ 50-hp. bucket motor.

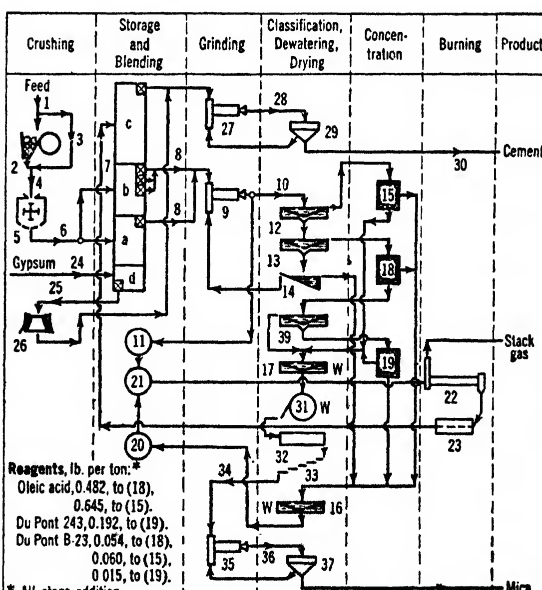

FIG. 23. VALLEY FORGE CEMENT CO.

Legend for Fig. 23—Continued:

8. 6-ft. table feeders, 1 to each bin; drawn alternately or proportionately as desired.

9. 2 @ 7 1/4×42 1/3-ft. 3-compartment wet-grinding tube mills, 20 r.p.m., 700-hp. synchronous motors. Charge: compartment 1, 13 tons @ 2 1/2- to 4-in. forged-steel balls; compartment 2, 12 tons @ 1 1/4- to 1 1/2-in. balls; compartment 3, 27 tons @ 7/8-in. balls. Liner: lifter-type, 3 1/4 in. thick new. Pulp density, 67% solids.

10. 1 of 10 @ 20(ID)×21-ft. steel storage and blend tanks. See Fig. 2. Mechanical (5-hp. motors) and air agitation. Pump; constant-head feeder.

11. 3 tanks as (10) for iron, silica, and for lime rock not needing correction.

12. 1 @ 30-ft. Hydroseparator (see Table 29).

13. 1 @ 10-ft. Hydroseparator (see Table 29).

14. 1 @ 11 2/3×23-ft. rake classifier, 8 s.p.m. (see Table 29).

15. 10 @ 66-in. sq. Fagergren cells (see Table 29).

16. 1 @ 125-ft. traction thickener, 69 m.p.r. (see Table 29).

17. 1 @ 80-ft. thickener, 34 m.p.r. (see Table 29).

18. 12 as (15). See Table 29.

19. 10 @ 36-in. sq. Fagergren cells (see Table 29).

20. 2 as (10) for blending (see Fig. 2).

21. 2 as (10) for storage (see Fig. 2).

22. 2 @ 11 2/3 and 8 3/4×223-ft. kilns, 0.94 m.p.r., 50-hp. d-c. geared motors.

23. 1 @ 4×16-ft. and 1 @ 3 1/2×13 1/2 primary reciprocating-grate coolers in parallel; 2 @ 3× 13 1/2-ft. secondary reciprocating-grate coolers in parallel.

24. Railroad cars, pan conveyor, bucket elevator.

25. 1 @ 6-ft. table feeder; 1 @ 3 1/2-ft. table feeder for gypsum.

26. 1 @ 28-in. Traylor reduction gyratory.

27. 2 @ 3-compartment 7 1/3(ID)×42 2/3-ft. tube mills, 20 r.p.m.; charge: 53 tons @ 1/2- to 3 1/2-in. forged-steel balls; liners, lifter-type, 3 1/4 in. thick new; 700-hp. synchronous motors.

28. 2 @ 7-in. Fuller-Kinyon pumps, 50-hp. motors.

29. 2 @ 16-ft. Sturtevant air separators, 75-hp. motors.

30. 2 @ 6-in. Fuller-Kinyon pumps, 60-hp. motors; storage silos; 8-in. carriage-mounted Fuller-Kinyon pump, 125-hp. motor; bulk loading and bag packing.

31. 1 @ 8×10-ft. drum-type filter, 2 1/4 m.p.r.; cake 23% moisture.

32. 1 @ 6 2/3×14-ft. nodulizer; nodules 19% moisture.

33. 1 @ 4×30-ft. reciprocating-grate drier.

34. 1 @ 12-in.×59-ft. screw conveyor, 27.7 r.p.m.

35. 1 @ 5×11-ft. ball mill, 29 r.p.m.; charge: 6,000 lb. @ 2-in. balls.

36. 1 @ 19-in.×38-ft. bucket elevator (6× 11-in. buckets), 240 f.p.m.; 1 @ 12-in.×21-ft. screw conveyor, 39 r.p.m.

37. 1 @ 10-ft. air classifier.

39. Hydroseparator.

Table 29. Quantities and assays in flotation plant at Valley Forge Cement Co.

Ref. No.	Item	Tons per day	Percentages			
			Of original feed	Solids	<200	$CaCO_3$

	Tailing	113	8.5	13.0	86.3	9.9
19	Mica flotation: Conc.	79	6.0	12.0	91.0	6.5
	Tailing	34	2.5	5.3	71.5	29.9

Summary. Two-stage crushing from run-of-quarry to <3/4-in. in jaw crusher and grate-type hammer mill; one-stage grinding to 93% <200-m. with circuit closed through two-stage Hydroseparation and one-stage rake classification. Correction by separate lime flotation of slime and fine sand fractions of raw feed and subsequent mica rejection from the sand tailing. Mica concentrate dried, ground, and sold. Slurry wet-blended and burned, with grate-cooler quenching.

Gulf Portland Cement Co. Fig. 24 (*41 # 10 RP 35*).

Location: Houston, Tex.
Capacity: 800 bbl. per day
Crudes: Oyster shell and clay; see Table 30; both purchased.
Power: Purchased.

33. 2 @ 5×22-ft. tube mills; 29 r.p.m.; 30,000 lb. 1 1/4-in. Concavex; 200-hp. motor.
34. 2 chain-bucket elevators; screw conveyor.
35. 1 @ 14-ft. Raymond air classifier.
36. 2 screw conveyors.
37. 1 @ 4-in. Fuller-Kinyon pump; 35,000-bbl. storage; bagging and loading.

FIG. 24. GULF PORTLAND CEMENT CO.

Summary. No crushing. Two-stage raw grinding with the circuit closed in the first stage by a screen. Wet blending. Two-stage closed-circuit clinker grinding; the first stage closed by screen and the second by air classifier.

SECTION 4

CRUSHING

1. INTRODUCTION

Definitions. Comminution is normally the first step in beneficiation of solid minerals. It is usually a stage process, utilizing in the successive steps machines especially suitable for reduction of particular sizes. The stages starting with the crude as mined or quarried and comprising successive reduction steps down to a final stage or stages employed for production of finest sizes are called CRUSHING. In contradistinction, comminution to 20-m. or finer is called GRINDING (Secs. 5, 6). There is a twilight zone in which the product is 6- to 10- or 14-m. limiting size, which is either crushing or grinding according to the type of machine used. PRIMARY CRUSHING is the first crushing stage; SECONDARY CRUSHING is the second, etc. COARSE CRUSHING includes crushing operations discharging at sizes 4- to 6-in. or coarser; INTERMEDIATE CRUSHING comprises operations taking feeds 6- or 8-in. maximum and making products down to $^1/_2$- or $^3/_8$-in.; FINE CRUSHING is reduction by crushing to $^1/_4$-in. or finer; the distinctions are not sharp.

CRUSHING MACHINES

Mechanical principles. Crushing is a mechanical operation in which a sufficient force is applied to relatively brittle solid particles in such directions that failure of the bonding forces in the particles is brought about. When the problem of crushing is thus approached, it becomes clear that crushing machines must be designed to exert either pushes or pulls on individual particles, since there are no other kinds of mechanical forces, and that the solid particles must be so introduced into and maintained in the force zone that the forces available can be applied to them. The study of the mechanics of materials has resulted in a classification of mechanical forces and of the structural elements for resisting them which, applied in reverse, supplies a terminology and basis for classification of crushing machines along mechanical lines. Thus the common load-bearing members are beams, columns, and ties; stresses induced in these by loading are tensile, compressive, and shearing; and the applied loads are stationary, slow-moving, or impact. Most crushers load the solid particles they crush as beams or short columns, but explosive shattering, whether by dynamite or by steam (Art. 11), loads them largely as ties. The induced stresses are mostly those of compression and shear, but tensile stresses arise in beam loading as well as in explosive shattering. The rate of loading in the majority of crushing machines is gradual; impact crushers form an important class, however; stationary loading is unknown.

With one or two relatively unimportant exceptions, all rock crushers taking coarse feeds apply pressure gradually to particles which take the load as simple beams or short columns. Two general types of mechanism are employed, *viz.*, (1) reciprocating breakers in which the crushing surfaces alternately approach and withdraw from each other, and (2) continuous breakers in which, in the crushing zone, there is continuous approach of the crushing surfaces to a substantially fixed predetermined minimum spacing. Reciprocating-pressure breakers include jaw, gyratory, cone, and gyrasphere crushers; continuous-pressure breakers are typified by rolls, single-roll crushers, and the so-called roller mills. Impact crushers form a group comprising mechanisms some of which, *e.g.*, stamps, load the particles primarily as short columns, whereas others load by striking particles in sus-

pension or by hurling them at high speed against stationary surfaces; hammer mills are typical of this latter class. Tumbling mills (ball mills, rod mills, etc.) utilize both continuous-pressure and impact mechanisms. Blasting, explosive shattering, and decrepitation (fire-setting) are tension-type breaking operations; all three are relatively unimportant as crushing operations, although blasting is, of course, pre-eminently useful in rock excavation.

A crushing machine must not only break the rock but must provide means for continuous presentation of uncrushed material to the crushing zone and continuous discharge of crushed material therefrom. Gravity is the force employed for presentation in the great majority of machines; gravity, gravity aided by the carrying force of a fluid (air or water), and gravity aided by the mechanical impulse of the crushing surfaces are the usual means of discharge. In some cases, however, gravity is used as a retarding force against the discharge impulsion of a stream of fluid by putting a weir-type baffle in the path of the discharge stream; in other cases discharge is regulated—and retarded—by a screen or similar perforate septum.

The size characteristics of a crushed product are determined, all other things being equal, by the mechanical principles employed in the crushing machine. Gradual application of load, loading particles as beams and short columns, and rapid and unhindered discharge from the crushing zone make for a granular product with a minimum of very fine material; impact, shear, and slow restricted discharge all tend to produce fines. Cumulative weight-per cent. size curves (see Figs. 15, 33, 49) for the product of crushers employing the first group of principles exclusively approach nearest to straight lines; the product of the grinding pan, which employs shear (abrasion) for breaking and interposes a high weir in the path of the water-borne discharge, plots as a highly concave curve. With doubtful exceptions the sizing curves of the products of all other comminuters fall between these limits.

Classification of crushers. Coarse crushers or breakers for rock are the jaw crusher, gyratory crusher, single-roll crusher, sledging or slugging rolls, and, occasionally, the hammer mill. Intermediate crushers are the reduction gyratory, cone crusher, hammer mill, stamp, and, occasionally, rolls. Fine crushers are rolls, hammer mills, short-head cones, fine-reduction gyratories, and stamps; certain grinding machines, *e.g.*, the rod mill (Sec. 5), may be used for fine crushing.

In general, jaw and gyratory crushers are pre-eminently adapted to breaking hard, tough, abrasive rocks. They are, therefore, used for the majority of metalliferous ores, which, it so happens, occur mostly with gangues of this description. The primary roll crushers and the hammer mill cannot break such rocks economically but are particularly useful with the relatively soft, friable and sticky rocks that are characteristic of many nonmetallic mineral deposits.

2. JAW CRUSHERS

Jaw crushers are reciprocating-pressure breakers, employing beam and short-column loading and having unhindered gravity discharge. They consist essentially of two crushing surfaces set at a small angle convergent downward, one fixed, the other movable and caused to approach and recede alternately from the fixed surface. The best-known type is the Blake, with movable jaw pivoted at top. The Dodge has the movable jaw pivoted at the bottom. The single-toggle type, in which the swing jaw is hung on an eccentric bearing on the drive shaft, and the horizontal-pitman machine, in which the pitman works directly on the bottom of the swing jaw, eliminating toggles, are relatively newcomers. Large primary jaw crushers are almost without exception of the Blake type. Single-toggle and horizontal-pitman machines are available as yet (1940) only in sizes up to 24×36-in. The Dodge (lever-type) has little or no present use in ore or rock crushing.

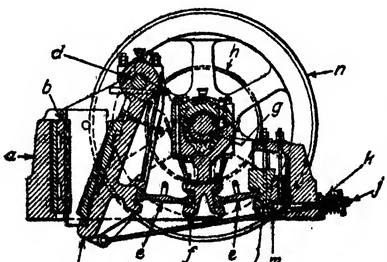

FIG. 1. Blake jaw crusher.

Blake breaker (Fig. 1) consists of a main frame *a* carrying a fixed jaw *b* and a movable jaw *c*, the latter pivoted at the top on the swing-jaw shaft *d*. The movable jaw is caused to oscillate by the action of toggles *e* and pitman *f* actuated by the eccentric *g* through the medium of pulleys *h* mounted on the drive shaft. The movable jaw is held up against the toggles by tension rod *j* and spring *k*. The rear toggle is seated against adjusting block *l*. The horizontal position of the rear toggle seat is changed by raising or lowering the block *m*

a Capacities are based on run-of-quarry thick-bedded limestone of moderate hardness; scalped at the upper end to insure ready nip, and at the lower end to remove material that would pass through without appreciable reduction; fed steadily at maximum capacity. See p. 13 for adjustments for feeds of different lithological character, and p. 07 for the effect of curved jaw plates. Apparent discrepancies in the listed tonnages reflect, in part, differences in degree of conservatism on the part of manufacturers and, in part, differences as to speed, weight, ruggedness, etc.

b Other sizes are made, particularly with a larger length-to-gape ratio, but those listed comprise the range of usual sizes.

by means of the bolt shown, thus permitting sufficient adjustment of discharge setting to take up for jaw-plate wear. In some crushers the position of the rear toggle seat is varied by shimming. The throw of the swing jaw may be varied slightly by raising or lowering block *l* or, in some makes, by varying the position of the rear toggle seat on block *m*. Heavy flywheels *n* are mounted on the drive shaft for the purpose of lessening the intermittent character of the load on the prime mover. A jaw crusher breaks rock only during that half of each revolution in which the movable jaw is approaching the fixed jaw; during the other half revolution the only work done is that in overcoming friction. Without flywheels a driving belt flaps badly and there is a tendency for the prime mover to run away on the unloaded half of the revolution while it is subject to a relatively enormous power draft on the loaded half. Flywheels average the load by storing energy during the unloaded half of the revolution and returning it during the loaded half. Table 1 presents essential data concerning Blake crushers, taken from manufacturers' catalogues. For many sizes the figures given have been checked against operating data and found to be conservative.

Main frame must be heavy enough to absorb vibration and strong enough to withstand heavy shock loads which produce tensile stresses around the mouth and near the base, and compression under the main bearings. There is considerable racking strain owing to uneven loading of the jaws. In small crushers (up to 15×30-in.) the frame is usually made in one piece, of cast iron (tensile strength, 20,000 to 30,000 lb. per sq. in.), high-strength cast iron (30,000 to 50,000), cast semi-steel (28,000 to 35,000), or cast steel (60,000 to 75,000). Recently certain manufacturers have made frames for small crushers of heavy welded steel plate, with heavy reinforcing ribs welded on. In large crushers a cast-steel frame, thoroughly annealed, is made in four pieces, two ends and two sides. Sometimes, when installation difficulties demand, the sides are made in two pieces, split horizontally. These frame parts are fitted together with carefully machined tongue-and-groove joints and secured by heavy bolts and tie rods of high-carbon steel (100,000 to 150,000 tensile strength) put in hot. Castings are heavily ribbed to give strength, while allowing considerable saving in weight. The principal tensile stresses are longitudinal, and the longitudinal tie rods are made sufficiently heavy to withstand these stresses without aid from the sides of the frame. Bearings for the pitman and swing-jaw shafts are best cast integral with the frame to aid in shaft alignment. The sides should be strengthened at these bearings by ribs, and in addition, by cross tie rods or by collars set in grooves or screwed onto the shafts. Cast-iron and semi-steel one-piece frames are sometimes reinforced with steel, shrunk on around the jaw openings and base. The CALUMET & HECLA-TYPE crusher has a one-piece ribbed frame reinforced by 3 @ 5-in. longitudinal bolts each side, 3 @ 4-in. bolts across the front end, and 2 @ 4-in. bolts across the rear end. By this expedient the weight of a 24×48-in. crusher is kept down to 80,000 lb. Modern trends are toward lighter crushers made of high-strength alloys. A crusher that is too light will, however, tend to shake either itself or its foundation to pieces.

Swing jaw is subjected almost entirely to bending loads. It is made of the same material as the frame, and, in large crushers, is similarly ribbed. It is shrunk or otherwise rigidly fastened to the swing-jaw shaft in order to bring the movement into bearings that are readily accessible for lubrication. The face of the jaw is machined to give an even bearing for the jaw plates. Some manufacturers make replaceable toe plates of special tough steel, *e.g.*, chrome steel, for the swing jaw, this being the only part of the swing jaw that is subjected to excessive wear.

Pitman stresses in crushers properly designed and built are almost wholly tensile, but torsional stresses sufficient to produce failure may be set up by improper toggles. In all but the smallest crushers the pitman is usually made of cast steel, thoroughly annealed. Every attempt is made to make it of the least weight consonant with the required strength. This end is ordinarily attained by the use of a heavy ribbed casting of box section, but one manufacturer makes a cast-steel cap and a toggle support separately and joins them together with annealed open-hearth forged-steel tension rods; while another welds together special shapes designed for maximum strength and rigidity with minimum weight. Several manufacturers of large crushers support the pitman on a nest of springs resting on a heavy cross-head on the frame. This reduces friction and consequent heating of the bearings, thereby saving power and lubricants and lessening the necessity for pitman cooling. At CALUMET & HECLA (*100 J 11*) substitution of a spring-supported pitman for the old style reduced the power consumption on a given crusher from 29 to 16 hp. Bolts holding down the pitman cap should have fine threads to aid adjustment.

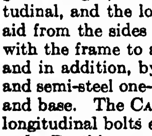

FIG. 2. Toggle with replaceable ends.

Toggles are subjected to compression only. The ends of the toggles, rolling or sliding in the toggle seats, are difficult if not impossible to lubricate properly, and since substantially the full crushing force is concentrated here they must be specially hardened to resist wear. Toggles are made of cast iron in small, cheap crushers. Small crushers of better grade have cast semi-steel or steel toggles with chilled ends. Large crushers are fitted with cast-steel toggles with chilled ends or with toggles made of alloy steels. One manufacturer makes toggles with replaceable ends (Fig. 2) for crushers of any type and size; one mill reports a life of 4 to 6 mo. for them. In many crushers the rear toggle is made the BREAKING POINT to relieve strain when uncrushable material gets into the jaws. In some cases this is accomplished by splitting the toggle along a diagonal plane as in Fig. 3 and riveting together with just enough metal to withstand all normal strains but insufficient to stand an excessive load. At TALISMAN MINE,

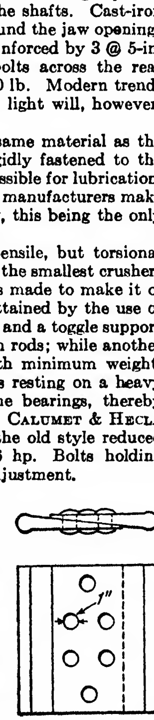

FIG. 3. Split toggle for jaw crusher.

N. Z., six 1-in. rivets in a 16×10-in. crusher sheared with a hammer head. At LYELL COMSTOCK, Mt. Lyell, twelve 1-in. rivets were used in a 12×20-in. crusher. Some manufacturers make the rear toggle itself of cast iron of such light section that it fails when excessive load is applied.

Life reported ranges from 45 days to several years, the majority less than a year.

Toggle seats are subjected to the same wear as toggle ends, but are less easily replaced and hence greater care is taken to insure long life. In small crushers they are made of hard, high-carbon steel; in large crushers, of manganese or chrome steel. From its properties, a chrome steel containing 1 to 2% chromium and about 1% carbon, hardened, should be the best possible material for this service. A rolling toggle, such as illustrated in Fig. 4*a*, with chrome- or manganese-steel seat should be superior to any form of sliding toggle such as illustrated in Fig. 4*b*, provided that it can be reasonably dust-proofed. One manufacturer uses steel shafting, suitably attached to swing jaw and adjusting block for front and rear toggle seats respectively, and another shaft, carried in the pitman, as a common bearing or rocker for both toggles, the toggle ends being correspondingly concaved for half-bearings. Heavy oil is forced into these bearings through flexible pipes.

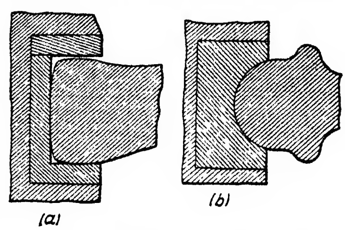

FIG. 4. Toggles and toggle seats.

Life reported in the mills ranges from 90 days to several years, the majority less than 1 year. Manganese-steel blocks on large crushers under fairly heavy load lasted from 1 to 2 years.

Shafts are subjected to enormous bending stresses and should be of large diameter to prevent deflection and consequent heating of bearings, as well as to guard against breakage. They are made of best quality high-carbon steel forgings, heat-treated and tempered, turned and polished, or of an alloy steel, such as Cr-Ni or Cr-V.

Bearings are heavily loaded even when the crusher is running light. They should, therefore, be of large diameter and as long as possible. In one-piece frames the bearings should be cast integral with the frame to aid in proper alignment of shafts. When frames are cast sectional, or welded, proper alignment is obtained by the use of ball-and-socket bearings. The pitman-eccentric bearing is water-cooled in most large crushers, even those in which the pitman is spring-supported. The pitman-shaft end bearings are often likewise water-cooled in large crushers (30-in. opening and upward). The best quality of hard babbitt is used. The frame bearings are babbitted in the frame in the small crushers, but in most larger crushers renewable semi-steel babbitted split bushings are employed. Interchangeable bearing liners save time when rebabbitting is necessary.

Flywheels are subjected to heavy strains by reason of the rapidly and greatly varying load on the crusher and must, therefore, be built especially strong. They are usually made of cast iron or semi-steel, but when cast in one piece, special precautions must be taken to insure against cooling strains. Some manufacturers cast rim, hub, and arms separately and thus eliminate shrinkage strain. One manufacturer keys the flywheel to the shaft with compression keys that allow slip with overloading, but this is probably an unnecessary precaution so far as flywheel breakage is concerned, and it is insufficient provision as a breaking point to save the crusher bearings in case of entrance of tramp iron. Rims on all large crushers are cored for pockets to allow barring over and are crowned when the flywheels are to be used as drive pulleys. Some manufacturers place weights on the rim to counterbalance the weight of the pitman.

At CALUMET & HECLA the end of the shaft is marked with an arrow to show the position of the eccentric and thus make it apparent which way to turn in order to ease off when the crusher is clogged.

Heat treatment of crusher steel is highly important. Harder (*115 J 314*) tested parts of jaw and gyratory crushers and rolls that had failed in service and found in all cases that the tensile and impact strengths, toughness, and hardness were markedly increased by simple heat treatment.

Drive of small crushers is by a single pulley carried on an extension of the eccentric shaft or bolted to a flywheel. The usual practice is to use two pulleys on crushers with greater than 24-in. width of receiving opening, if drive is from a countershaft, but when direct belt drive from a motor is employed, one pulley is ordinarily used. At CREIGHTON mines, Ont., a 30×42-in. crusher is driven by two 100-hp. motors. When two drive pulleys are used, each should be sufficient for independent drive. The principal objection to single-pulley drive is the unbalanced side pull on the bearings. This is not serious, if the shaft and bearings are properly designed. In some large crushers the flywheels are replaced by extra heavy flanged drive pulleys or rope sheaves. Lenix system or some form of multibelt drive is frequently used for driving crushers of all sizes on account of the advantage of compactness in installation. Ordinary pulley dimensions are based on transmission of 1 hp. per inch of drive belt traveling at 1,000 f.p.m.

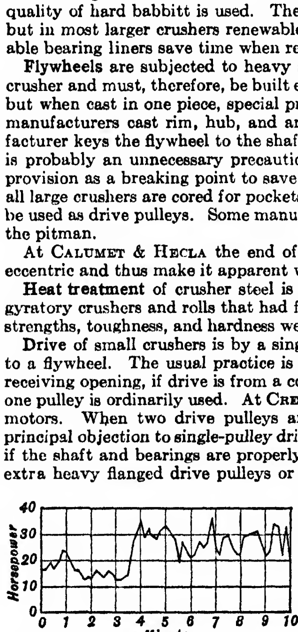

FIG. 5. Power draft of 18×36-in. Blake crusher.

Installed horsepower is generally well in excess of the average drawn, in order to take care of the starting load, which may run to 100% in excess of full-load average. If, however, the motor has temporary overload capacity sufficient to carry the starting load, a motor with full-load rating of 125% of average full-load power will take care of instantaneous peak loads. The shape of a jaw crusher power-draft curve at WITHERBEE SHERMAN & Co. is given in Fig. 5. This shows fluctuations from 19 to 37 hp. within a minute for an 18×36-in. crusher running under full load (186 r.p.m.; 8- to 10-in. max. size of feed; <4-in. product; 102 t.p.h.). Practice in respect to motor installations varies widely (see Table 8): the average ratio of full-load to installed power is probably near

0.85. If this is increased much there will be serious speed reduction with consequent clogging under full-load conditions. Fig. 6 gives average values for installed horsepower *vs.* dimensions of receiving opening. The curve has a semi-rational basis in that the product plotted as ordinates, *viz.*, *LG*, is approximately equal to half the working area of the swing jaw, which area, in a fully loaded crusher, should be proportional to the power draft.

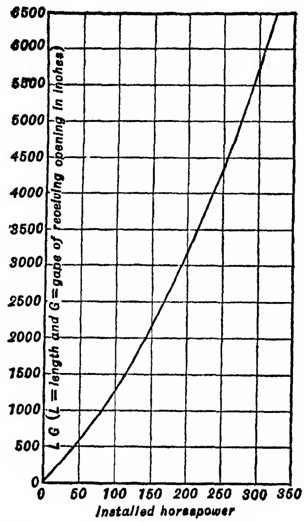

FIG. 6. Installed horsepower *vs.* area of receiving opening for Blake-type jaw crushers.

Hand of drive is ordinarily specified as of an observer facing the crushing end of the machine. Some crushers are made with a symmetrical pitman shaft, in which case the hand is interchangeable on the job. Others must be specified on purchase.

Lubrication of jaw crushers is difficult on account of the great pressures on the bearings and the large amount of dust and grit present. All well-built crushers use forced feed of either grease or oil. Because of the way in which exuding grease forms a collar that excludes dust and grit, most manufacturers use grease fed by means of compression cups with automatic or manual feed. Some crushers are fitted with compression feed to the under side of the pitman-eccentric and pitman-shaft bearings and large grease or oil reservoirs on top for gravity feed. Toggle seats are most difficult to lubricate, and that design of toggle and seat is best that minimizes the need for lubrication.

Consumption of lubricant as reported by various mills is shown in Table 8. The enormous differences are apparently due to differences in crusher duty, since high consumption of lubricant corresponds to heavily loaded crushers and *vice versa.* Difference in character of lubricant will also cause tremendous differences in consumption and friction losses. The lubrication engineers of the large oil companies have usually had considerable experience in the lubrication of heavy machinery; their recommendations as well as those of the machine manufacturer should be given close consideration. It may be taken without question that any haphazard choice of lubricant is almost certainly wrong and that an independent decision of a plant operator or purchasing agent made without careful and prolonged testing for the specific service will probably result in less efficient lubrication than that which would be recommended by the sales engineers of either the machine manufacturer or of the lubricant maker.

Jaw plates. The principal wear on the crusher comes on these and on the cheek plates. They are, therefore, made replaceable. Further, wear on the jaw plates is uneven, and in order to lessen the amount of metal discarded in the form of worn plates they are made reversible. In the case of large crushers with sectional jaw plates they are also made interchangeable. Thus in a small crusher, when the jaw plates become worn at the throat, where wear is greatest, they are turned end for end and their life is practically doubled. When plates are sectionalized horizontally, two wears are added for each such sectionalizing. When the form of surface corrugation permits, further increase in life of plates is gained by also sectionalizing vertically, when four wears at the throat can be had from each section. In addition to longer life, sectionalizing makes for ease in handling, which is a great advantage in large crushers. Materials used for jaw plates are chilled iron, white iron, high-carbon cast steel, forged steel, manganese and chrome steels. The great majority of plants use manganese-steel plates. This material is particularly fitted for such service on account of the fact that it is tough and that surface abrasion produces rapid and marked surface hardening. One special form of jaw plate is made of forged and rolled chrome-steel bars cast-welded into a back of open-hearth steel and subsequently tempered. This gives a hard chrome-steel crushing surface, while the untempered back is tough and resists cracking. Chilled steel wears unevenly because it is initially uneven in hardness. CALUMET & HECLA uses chilled cast-iron plates for crushing soft amygdaloid and manganese steel for the hard conglomerate. The main frame and swing jaw are carefully surfaced to give full, even bearing to the jaw plates, or the plates may be backed by zinc or hard babbitt. Plates in small crushers are usually wedged in; those in large crushers are bolted in. One maker places a buffer plate between the wearing plates and frame to take up any wear on frame due to the abrasive action of grit, in case the liner plates loosen and vibrate. Loose plates, or plates unevenly or incompletely backed, may fail by bending stress. To guard against such failure plates in some large crushers are made 5 $^1/_2$ to 6 in. thick.

Life of jaw plates varies according to the material used and service required. (See Table 8.) Three to six months is an average life for manganese-steel plates in ordinary service. One plant reports 40 days for manganese-steel plates in an 18×30-in. crusher handling 1,500 tons per 24 hr. of hard granitic ore. Another reports 2 to 4 years for plates of the same material in a 36×42-in. crusher handling 4,000 to 5,000 tons per 24 hr. of hard slate with some quartzite. The consumption of manganese steel,

including waste on rejection, is from 0.01 to 0.06 lb. per ton of rock crushed. The consumption of chilled iron in small crushers ranges from 0.02 to 0.2 lb. per ton and averages about 0.1 lb. per ton. Johnson (*101 J 907*) gives the following comparative figures on chrome and manganese steel in the same service: chrome steel, weight of plates, 921 lb.; cost f.o.b. mill, $96.93; life, 70,206 tons: manganese steel, weight, 740 lb.; cost, $72.62; life, 86,478 tons. It must be remembered that manganese steel, as well as all other metals, varies markedly in grade and wearing qualities. Waterhouse (*38 Aa 107*) cites a set of manganese-steel jaw plates of Sheffield manufacture that served to crush 6,100 tons in a small crusher against a life of 4,500 tons for local Australian plates of substantially the same manganese content. Del Mar (*40 MEW 687*) recommends 13% Mn as the best alloy.

Building up worn plates by surface welding was practiced (1939) by 3 out of 30-odd plants reporting; the practice is increasing rapidly (1943).

Time required to change jaw and cheek plates is from 1 to 3 hr. for crushers up to 24×36-in. One mill using a 36×42-in. crusher reports 8 hr. to make a change of plates.

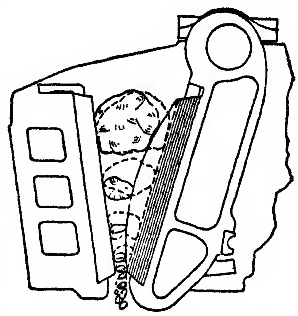

Fig. 7. Diagrammatic comparison of reductions with straight and with curved jaw plates. (*After Allis-Chalmers Mfg. Co.*)

Shape of plates. Jaw plates are made in two general shapes. Older practice, still represented by the majority of installations, used plates in which longitudinal surface elements were straight lines. Recently plates with these elements convex outward have been introduced. They are usually placed on the swing jaw only, but some manufacturers convex both jaws. One manufacturer makes the fixed jaw convex and the lower end of the swing jaw concave. The effect of curvature on the shape of the crushing zone is shown in Fig. 7. The theoretical result of this difference is indicated in Fig. 8, in which the numbered horizontal lines delimit zones which are defined, on a rock-size basis, as the successive downward positions of particles broken to just the closed dimension between the jaws at any level and falling successively to new seats on recession of the swing jaw. Thus a piece of rock which just seats along the line *1* with the swing jaw in closed position will just seat along line *2* when the jaw is in open position, and the vertical distance from *1* to *2* represents its advance for this movement. If this particle, seated at *2*, broke to just the extent of the forward movement of the jaw at *2* on the next forward stroke, it would advance to *3* on the next recession, etc. It is clear from the figure that with the straight jaw the areas of the trapezoidal spaces between the successive position lines decrease downward, and, therefore, that the large pieces in progressive zones will have progressively less relative space, *i.e.*, these zones will have a progressively increasing tendency to choke, this tendency reaching a maximum at the throat. With the curved plate, the minimum trapezoidal area occurs well above the throat, and thereafter the larger particles have room to spread out as they progress, thus permitting not only increasingly free movement of themselves but also increasingly ready passage between them and out of the crushing zone for the fine material.

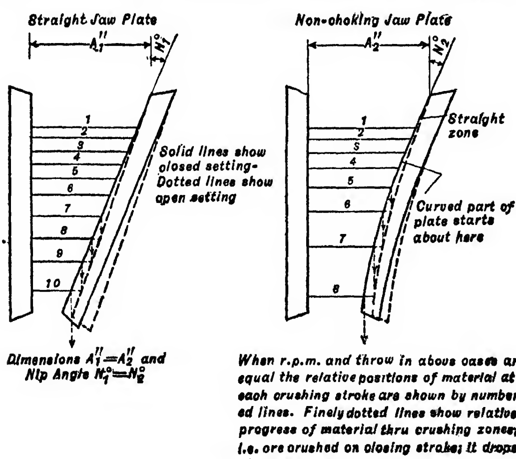

Fig. 8. Comparison of size zones with straight and curved jaw plates. (*After Allis-Chalmers Mfg. Co.*)

The difference in shape in the two crushing zones causes a number of differences in operation and performance.

1. Since the normal choking point, *i.e.*, the point at which the volume of coarsely crushed rock becomes too great for free fall past the next lower horizontal section of the crushing zone, is moved upward with the curved plate to a point well above the throat, it occurs where the motion of the swing jaw is relatively small and the percentage of fines is low. Hence the tendency to compact the material in the zone is much less than at the throat, and much less choking occurs than with the straight plates.

2. The plate area over which fine crushing occurs is much greater with the curved plate; consequently the depth of plate wear per ton crushed at any given point in the fine-crushing zone is decreased, with correspondingly longer duty in the machine, less plate reject loss on removal, and so less plate consumption per ton crushed.

3. Throw may be decreased with the curved plate, since there is no necessity to free the throat. The machine may, therefore, be speeded up, which Fahrenwald *et al.* (*138 #12 J 45*) found would cause an increase in new surface produced with no corresponding increase in power consumption. The combined

result of these two changes is a finer and more uniform product with the curved plate for the same open setting—since the higher the speed the more nearly the product size corresponds to the closed setting—or, conversely, a higher capacity and higher tons per hp-hr. to the straight-plate maximum size.

4. For the same minimum throat opening the angle at the mouth is greater with the curved plate, or the GAPE (shorter dimension of receiving opening) must be smaller. Hence there will be more difficulty with initial nip (see p. 11) and a greater tendency to choke at the mouth. Curved plates should not, therefore, be substituted for straight when the crusher feed contains a large percentage of material near the crusher gape in size.

It is claimed that the use of curved plates will increase capacity over that with straight plates 33 to 50%. Operating confirmation is not yet available.

Crushing surface of jaw plates is made in a variety of forms. For relatively fine crushing and brittle rock, plane surfaces are best; for all-around coarse work, a surface corrugated vertically with 90° ridges as shown in Fig. 9 is best, the pitch of the corrugations being roughly equal to the maximum size of product desired. In crushing soft tough rock, ridges are likely to pulverize locally without effecting a break, with the result that material hangs up at the mouth and the crusher clogs. A partial remedy is to place a half-worn plate opposite a new one, but if the condition is aggravated, plates with the projections blunt and rounded (WAVE JAWS) should be used. These concentrate the breaking load without excessive local pulverization. They are especially suited to tough, slabby rock, like slate. Waved plates are used in several LAKE SUPERIOR copper mills in preference to corrugated, since they allow mass copper that has caught to be freed by working sideways, which cannot be done with corrugated plates.

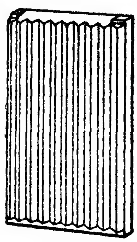

FIG. 9. Corrugated jaw plate.

Cheek plates take wear on the sides of the crushing opening. The materials used are ordinarily the same as for jaw plates. The surfaces are plane. The plates are wedged in in small crushers and bolted through in large. The life of manganese-steel cheek plates is the same or slightly less than that of jaw plates of the same material, and metal consumption is usually less than 0.01 lb. per ton crushed. Chilled-iron plates have about one-quarter to one-third the life of manganese-steel.

Sectionalizing. Additionally to the sectionalization of the main frame already noted, most makers are prepared to sectionalize crushers up to 15×24-in. size to maximum weights of 300 lb. upward, the cost per lb. increasing with the extent of sectionalization. This type of construction is almost essential for installation in isolated rugged regions or for underground service. Total weight of sectional crushers is ordinarily less than that of the standard crusher of the same size. This fact, added to the inherent lessened rigidity, usually results in increased vibration with increased maintenance costs for the sectionalized machine.

Manufacturers. Acme Road Mach. Co., Allis-Chalmers Mfg. Co., Austin-Western Road Mach. Co., Birdsboro Steel Fdy. & Mach. Co., Chalmers & Williams, Colorado Iron Wks. Co., Denver Equipment Co., Eimco Corp., Farrell Fdy. & Mach. Co., Gibson, W. W., Gruendler Crusher & Pulverizer Co., Jeffrey Mfg. Co., Kennedy-Van Saun Mfg. & Eng. Corp., McLanahan & Stone Corp., Mine & Smelter Supply Co., Morse Bros. Mach. Co., Pennsylvania Crusher Co., Smith Eng. Wks., Stearns-Roger Mfg. Co., Straub Mfg. Co., Sturtevant Mill Co., Traylor Eng. & Mfg. Co., Webb Corp.

Adjustments of Blake crushers are (*a*) width of discharge opening, (*b*) THROW, *i.e.*, the distance traveled in each direction by the jaw at each revolution of the drive shaft, and (*c*) speed.

Width of discharge opening is adjusted by changing the length of the toggles, changing from worn to new or from thin to thick jaw plates, or by a wedge or shim adjustment of the rear toggle seat. Ordinarily only sufficient toggle-seat adjustment is provided to compensate for jaw-plate wear, and this adjustment is made from time to time as plates are worn down. Change in length of toggles is usually made only when the duty of the crusher changes and a wholly different size of product is desired.

Throw, in Blake crushers, is measured at the throat. It is adjustable in some crushers by a device for raising or lowering the rear toggle block and thus changing the angularity of the toggles, but ordinarily throw adjustment involves a change in the eccentric and requires a new pitman or, at the least, a new eccentric. Throw ranges from about $^3/_8$ in. as the minimum in small crushers up to 1 in. minimum in large crushers. The maximum throw is about three times the minimum figures.

The principal factor determining the length of throw is the character of rock to be crushed. If the rock is hard and brittle, so that the jaws do not pulverize locally and deformation prior to fracture is not great, the minimum throw may properly be employed. If the rock is of such character that the reverse situation prevails, and there is local pulverization and a tendency for the rock to crack and be deformed under load but not to fall apart, then the maximum throw should be used. Firm quartzitic and acid rocks generally require minimum throw; tough basic rocks, highly crystalline rocks, slabby rock, and decomposed rocks in general require the greater throws.

Speed can be varied only by change in the speed of the prime mover or by a change in pulley ratios in the power-transmission chain. Change in speed affects capacity and power consumption. It has no marked effect on the size of product with straight jaw plates, but increase in speed with curved plates tends to give a finer discharge.

LAKE SUPERIOR rock-house practice varies the speed according to the hardness of rock crushed (*100 J 55*). At QUINCY, breaking soft amygdaloid, the speed is 140 r.p.m.; at CALUMET & HECLA,

with a feed of hard conglomerate, the crusher is run at 175 r.p.m., and at COPPER RANGE, crushing dense amygdaloid, the speed is 185 r.p.m. Excessive speed causes heating. At MOOSE MOUNTAIN (*99 J 974*) a 24×36-in. crusher overheated when run at 250 r.p.m. but gave no trouble when run at 180. There was, however, an accompanying decrease in capacity.

Size of feed that can be taken by a jaw crusher continuously, *i.e.*, without clogging at the mouth, depends upon the gape, the allowable nip angle (Art. 8), and the angle between the jaw faces. Since the latter angle rarely exceeds 24°, and the maximum allowable nip angle for ordinary rock is about 33°, the latter two factors are not important except in the case of unusually slippery feeds. With such feeds JOHNS-MANVILLE (*113 J 674*) hold the nip angle to 18°. The essential requirement is that the lump enter the receiving opening far enough so that the bearing points on the jaws are sufficiently below the top that local pulverization at the contact points on jaw approach will not result in extrusion of the particle and loss of grip. Practically this means that the largest particles should seat with the contact points with the jaws at least one-quarter and better one-half the particle diameter below the top of the jaws. This works out that the thickness of the largest particle should not exceed 80 to 90% of the gape. Crushers will operate with occasional large particles seating higher than this, but mouth clogging is frequent if the crusher is being pushed.

Less throat clogging will occur with straight jaws, and the tonnage of material coarser than the open setting that can be crushed per unit of time will increase, if undersize is screened out ahead of the crusher and by-passed.

Reduction ratio is ordinarily defined broadly as the ratio of size of feed to size of product in a crushing operation. It is useful as a measure of what a crusher can do or is doing in the way of size reduction; as a partial indicator of the mechanical strains (DUTY) under which a crusher works; as an element in the determination of crusher capacity; and as a factor in the determination of crusher efficiency. No one method of calculation of the ratio gives a figure which is useful in all of these considerations; for this reason several reduction ratios are defined herein and designated by suitable names.

Limiting reduction ratio (R_L) is the ratio of the aperture passing all feed to the aperture of the same shape passing all product. It is the quantity normally understood to be meant when reduction ratio is referred to without further definition. It should be noted, however, that in calculating this ratio for primary crushers, for which sizing tests of feed are rarely, if ever, available, the usual designation for maximum size is the spacing of the stope or bin grizzly, and that this measures maximum *thickness* of feed, while a square- or round-mesh screen is normally used to size the product, and this measures intermediate dimensions of particles. Hence one or the other of these measurements must be adjusted before a correct limiting reduction ratio may be stated.

Shape factor. Shepard (*RI 3432*) has shown that the average ratios of minimum (t) : intermediate (w) : maximum (l) dimension of particles of the same broken rock are remarkably constant through a wide range of sizes and that the ratio of intermediate : minimum dimension, called herein the shape factor (F_s), ranges from about 1.7 for cubic-breaking rock to about 3.3 for relatively slabby rock; it may exceed the latter figure greatly for thin-bedded sedimentaries, some schists, slates, and the like. Hence, multiply mine-grizzly aperture by F_s, or divide the ring size passing all product thereby, in order to reduce the dimensions to a corresponding basis for ratio calculations.

Size of run-of-quarry rock is frequently given in terms of shovel-dipper sizes; this is equivalent to a square-mesh screen size.

$$R_L = \frac{w_f}{w_p} = \frac{t_f}{t_p} = \frac{F_s t_f}{w_p} \tag{1}$$

where w and t are width and thickness respectively of a particle, and subscripts f and p denote respectively feed and product.

Apparent reduction ratio (R_A) is the ratio of the effective gape to the effective setting (s_e) of the crushing machine (open setting for low-speed primary crushers and closed setting for the high-speed secondaries). This ratio bears no necessary relation to actual size reduction as measured by screens. It is useful as a statement of what a rugged machine sufficiently powered could do in the way of maximum particle-size reduction at one pass. Minimum standard open settings for most jaw crushers permit a ratio of gape to open setting of 8 or 10 : 1; the ratio for recommended maximum open settings is usually between 3 and 4 : 1. *Miller* states that this ratio with straight-jaw machines should not exceed 6 on tough rock or 8 on soft rock. The range reported in Table 8 is 3 to 10.3, and averages 5.6; the average tends to be somewhat smaller for small crushers than for large.

$$R_A = \frac{0.85G}{s_e} \tag{2}$$

Working reduction ratio (R_W) is the ratio of thickness of largest feed particle to effective set (s_e) of crusher. It indicates, when taken with the total tonnage passing through a machine, and compared with average performances or manufacturer's ratings for machines of the same size, the character of the duty.

$$R_W = \frac{t_f}{s_e} = \frac{w_f}{F_s s_e} \tag{3}$$

Mean reduction ratio purports to be the ratio of average sizes of feed and product. True average size of crushed solids is, unfortunately, not capable of determination with our present knowledge (Sec. 19, Art. 18). Bond (*139 #7 J 49*) gives a method of approximating mean reduction ratio for the granular portions of fine feed and product. Plot cumulative per cent. retained against logarithm of screen size for both feed and product, using rectangular paper. (If testing sieves with a standard interval are used, size or ordinal numbers may be assigned to these, increasing by a constant from screen to screen, starting *e.g.*, with 1 for the limiting screen of the feed, thus 1, 2, 3, etc., to the finest screen used. If these ordinal numbers are then plotted directly against cumulative per cent. retained, on rectangular paper, the actual screen sizes are plotted on logarithmic scale. Fig. 10 shows such a plot.) A reduction-ratio curve may be plotted from the sizing curves as follows: (1) Assume that the abscissa of the mid-per cent. point for each approximately straight-line segment of the sizing curves is the average size of the material plotted over that particular segment; (2) select segments sufficiently short along the cumulative-per cent. axis so that both sizing curves are substantially straight over the range; (3) differences between ordinal numbers of feed and product at the selected mid-per cent. points are partial reduction ratios corresponding to the weights of feed material comprised within the particular sizing-curve segments. Plot these against cumulative percentage at each point and connect the resultant points in a smooth curve. It will be noted that further extension of the sizing curves must result in substantially parallel lines substantially parallel to the axis of ordinal numbers and that, therefore, the corresponding spread on the ordinal-number axis between mid-per cent. points will increase rapidly. Hence the reduction-ratio curve, if extended farther upward, would bend sharply to the left. It is definitely questionable, however, whether such geometric behavior represents actual physical fact. Certainly in the case plotted, representing operation of coarse rolls set at about 4-mm., it is not legitimate to conclude that the <0.15-mm. material in the feed suffered more severe crushing, as indicated by a higher reduction ratio, than did the coarse fraction of the feed. For this reason it would seem that only the substantially straight portion of the reduction-ratio curve is significant. The value of the mid-per cent. point of this curve may be defined as the MEAN REDUCTION RATIO.

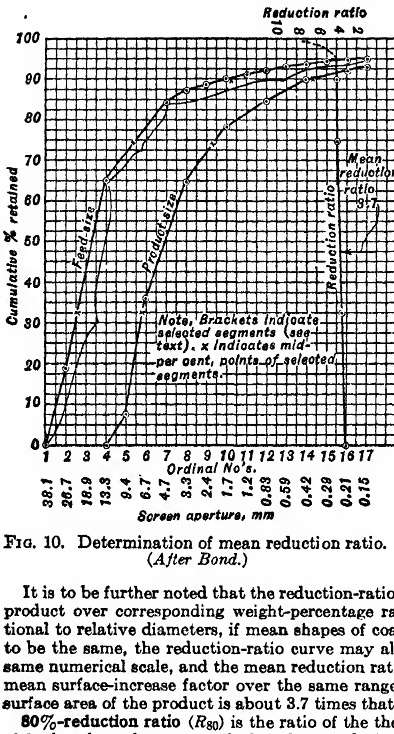

FIG. 10. Determination of mean reduction ratio. (*After Bond.*)

It is to be further noted that the reduction-ratio curve is a statement of relative diameters of feed and product over corresponding weight-percentage ranges. Since relative surfaces are inversely proportional to relative diameters, if mean shapes of coarse and fine fragments of the same rock are assumed to be the same, the reduction-ratio curve may also be taken as a curve of surface increase, using the same numerical scale, and the mean reduction ratio over the granular range is numerically equal to the mean surface-increase factor over the same range. For example, over the range of sizes plotted, the surface area of the product is about 3.7 times that of the feed.

80%-reduction ratio (R_{80}) is the ratio of the theoretical square-mesh apertures that would pass 80% of feed and product respectively. It was devised (*153 A 319*) to escape from the inaccuracy introduced into calculations of limiting reduction ratio by the presence of a small proportion of coarse slabby material. Thus when crushing slate or schist, for example, in a jaw crusher, a few slabs the full width of the crushing zone may discharge; since the width of these is the same as the width of the maximum feed particle, $R_L = 1.0$. But study of a large number of sizing curves shows that the effect of tramp coarse material on the shape of the curve has disappeared by the time the 20% cumulative weight-retained ordinate is reached, while the characteristic parts of feed and product curves have not yet converged enough to affect the value of the ratio materially.

Values of w_{80} (see below) for feed and product may be read directly from sizing curves or calculated from the screen tests by Eq. 4. The calculation is based on the assumption of straight-line size variation between the cumulative-weight-per cent. points that bracket 20%.

$$w_{80} = w_c - \frac{(20 - c)(w_c - w_f)}{f - c} \tag{4}$$

where w_{80}, w_c and w_f are respectively the 80%-size, and the apertures of the coarser and finer screens that bracket the 20% retained size, and f and c are, respectively, the cumulative percentage weights retained on w_f and w_c.

$$R_{80} = \frac{w_{80f}}{w_{80p}} \tag{5}$$

When screen tests are not available, 80%-sizes may be approximated, the method differing according to the data available. Thus run-of-mine and run-of-quarry rock may, without great error, be assumed to have a straight-line cumulative per cent. weight-retained curve, so that if the limiting-grizzly spacing (t_g) is known

$$w_{80f} = 0.8F_s t_g \tag{6}$$

Characteristic curves for the products of various crushing machines are given in Figs. 15, 33, 42, 43, and 49, in terms of percentage of limiting screen, and the corresponding 80%-size w_{80p} may be approximated from these, if the effective set is known. In general w_{80p} ranges between $0.5w_L$ and $0.6w_L$ (where w_L = aperture of limiting screen) for jaw or gyratory-type crushers; between $0.6w_L$ and $0.75w_L$ for open-circuit free-crushing rolls; $0.3w_L$ to $0.4w_L$ for choke crushing in rolls with a medium set; and $0.2w_L$ to $0.25w_L$ for choke crushing with fine set and heavy circulating load.

If no particle-size data are available, rough approximation of w_f and w_p and the corresponding 80%-sizes may be made in certain instances. Thus if a crusher with fixed gape G is being fed with as coarse material as it will take without bridging, the limiting feed thickness (t_{Lf}) may be taken equal to $0.85G$ and limiting thickness of product (t_{Lp}) = s_e. For rolls fed to just nip $t_{Lf} = s_e + D/40$ (from Eq. 13) and for rolls free-crushing $t_{Lp} = s_e$.

If unscalped feed (subscript u) is sent to a crusher, the undersize therein will affect the position of the 80%-point of the feed and may affect that of the product. Since such undersize is not ordinarily changed appreciably in size by passage through the crushing zone, its effect on R_{80} should be eliminated. If sizing tests are available, the correction may be made by replotting after eliminating from the feed all material having thickness less than the effective set. If sizing tests are not available, estimates of correction may be made as follows:

For feeds comprising run-of-mine or run-of-quarry rock, the curves for unscalped and scalped (subscript $_s$) feeds will approximate $\overline{AC}$ and $\overline{ABC}$ (Fig. 11, item a) respectively, $\overline{FD}$ and $\overline{FE}$ are the corresponding 80%-sizes, $\overline{AB}$ is the aperture of the scalping screen, and $\overline{DE}$ is the additive correction to $\overline{FD}(=w_{80u})$ to give $\overline{FE}(=w_{80s})$. From Fig. 11 it is apparent that $\overline{DE} : \overline{AB} = 20 : 100$ or

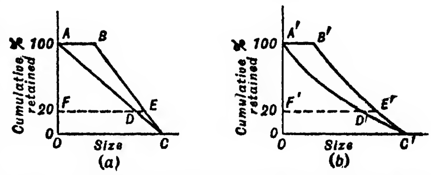

FIG. 11. 80%-points for scalped and unscalped broken rock.

$$w_{80s} = w_{80u} + 0.2w_s \tag{7}$$

where w_s is the aperture of the scalping screen. But $w_{80u} = 0.8\,F_s t_g$ (from Eq. 6), hence

$$w_{80s} = 0.8F_s t_g + 0.2w_s \tag{7a}$$

If the feed is the product of a preceding crusher, the general shape of the sizing curve will be concave as in Fig. 11, item b, but the relationship between $\overline{D'E'}$ and $\overline{A'B'}$ is substantially the same as that between $\overline{DE}$ and $\overline{AB}$ and Eq. 7 may be applied.

R_{80} at 24 plants reported in Table 8 ranged from 2.2 to 8.3 and averaged 4.5.

Nip angle in jaw crushers is the angle formed by the jaw faces. The usual range is from 18° to 24° at open setting for straight-jaw machines. The nip angle increases as the jaw moves forward; hence, if the angle is too large with the jaws open the unfavorable condition is aggravated as the jaw closes. Kennedy (*17 MMt 139*) claims that this fact decreases the effective gape of a Blake jaw crusher about 25%.

Capacity of a Blake crusher (and of other reciprocating pressure-type crushers) is equal to the product of the integrated volume of the stream of crushed material passing the discharge opening per unit of time and the density of the stream. As such it is affected by the area of the discharge opening at open setting and by such elements of operation as affect the speed at which material is presented to the discharge opening, *e.g.*, character of rock, moisture content, throw, reciprocations per minute, nip angle, shape and surface character of jaw plates, method of feeding, and size reduction effected.

Hersam (*68 A 463*), working with a small crusher, found that SPECIFIC GRAVITY, CONSISTENCY, and for hard rock, a resistance to breaking that may be defined as CRUSHABILITY, all affect capacity. The effect of variation in DENSITY is indicated by Table 2. The column headed "Relative volumes per hour" shows that there is a distinct trend toward the passage of a larger volume of dense material through the crusher in a given length of time.

Table 2. Effect of density of feed on capacity of jaw crushers (*after Hersam*)

Material	Sp. gr.	Relative tons per hour	Relative volumes per hour
Coke	1.1	100	100
Coal	1.9	170	100
Granite	2.7	381	159
Stibnite in quartz	3.0	436	159
Chalcocite in quartz	4.4	641	162
Galena in quartz	6.2	950	172

FIBROUS MATERIALS, such as rich asbestos rock, and CLAYEY ROCK may be expected to cause capacity to fall well below catalogue figures. Sticking of clayey materials may be considerably lessened by allowing a trickle of water to run into the crusher with the feed. This tends to lubricate the crushing faces sufficiently to allow the compressed material to slide forward as the movable jaw recedes and thus to work through the crusher. In crushing SLATE, which cleaves easily and tends to discharge from the crusher in slabs much larger in one or two dimensions than would be expected from the crusher setting, there may be considerable reduction in capacity, owing to the measures that must be taken to prevent such discharge.

At Stasso Milling Co. discharge of slabs was prevented by attaching prongs at 6-in. intervals to the bottom of the swing jaw, these prongs projecting across the throat and under the fixed jaw plate. The feed to the crusher ranged from pieces that would just enter the 15×24-in. receiving opening to pieces that could pass through without any crushing. The crusher was set for a minimum opening of 1 5/16 in. and had a throw of 1 in. The capacity without prongs was 25 t.p.h. and the product contained about 2% of slabs that stayed on a 4-in. screen. The capacity with prongs was 20 t.p.h., but there was no slabby material in the product. The average size of the product was not greatly altered.

Table 3. Relative toughness of rocks (*after Snelling*) **and crushability factors** (*k*) **for use in Eq. 10**

Rock	Relative toughness	k
Limestone	1.0	1.0
Dolomite	1.0	1.0
Gneiss, coarse-grained	1.0	0.95
Syenite	1.0	0.95
Andesite	1.2	0.90
Slate	1.2	0.90
Granite, coarse-grained	1.2	0.90
Chert	1.5	0.80
Gabbro	1.6	0.80
Quartzite	1.9	0.80
Rhyolite	2.0	0.80
Granite, fine-grained	2.1	0.80
Diorite	2.1	0.80
Basalt	2.3	0.75
Diabase, fresh	3.0	0.65

Many attempts have been made to quantify the crushability of hard rocks, but none of them can be accepted as other than rough approximations. Snelling (*28 Proc. Eng. Soc. W. Penna., No. 8*) studied the effects of explosives on a variety of rocks and summarized his conclusions as in Table 3. Hersam found that the capacity of a jaw crusher on granite was about 90% of that with quartz; with trap, 83%. Allis-Chalmers Co. (*PC*) estimate that quartz, quartzitic ores, and firm (but not tough) ores generally can be crushed at a rate equal to catalogue figures; rates for tough acid igneous rocks are about 85 to 90% of catalogue ratings, and for tough basic igneous rocks such as traps and diabases, about 75 to 80%.

Moisture has very little effect on primary-crusher capacities except with unusual clay-bearing rocks. But in secondary crushers with unscalped feeds, moisture contents of 3 to 6%, which concentrate, of course, in the fines, may reduce capacity 50% or more owing to caking in the fine-crushing zone.

Throw, if sufficient to effect break, controls capacity primarily through its effect on the tendency to choke. Large throw permits relatively large relief of compressed grain mixtures in the choking zone, with corresponding acceleration of discharge of fines.

Speed. Capacity increases with speed, but the increase is not proportionate (see Table 4 and also p. 08).

Nip angle. The effect on capacity as found by Hersam is shown in Table 5. When the angles are near those common in practice but little effect is to be noticed.

Table 4. Effect of speed on capacity of jaw crushers (*after Hersam*)

Revolutions per minute	Relative tons per hour
160	100
255	144
304	171
348	174
534	179
629	246

Table 5. Effect of nip angle on capacity of jaw crushers (*after Hersam*)

Angle of nip, degrees	Relative tons per hour
30	100
27	102
20	116
14	114

Method of feeding. Primary crushers are rarely fed to the limit of capacity. Such feeding requires a surge bin with nonclog outlet, a feed of roughly cubic character sized to a maximum thickness of about 85% gape, with all material that will pass the open setting removed, an efficient variable-rate feeder, and a vigilant attendant. Best average feeding conditions probably do not reach more than 75% of the maximum feed rate, and feeding with no storage between mine or quarry and crusher, and consequent intermittent charging probably averages nearer 25% than 50% of crusher capacity.

Table 6. Effect of reduction ratio on capacity of jaw crusher (*after Hersam*)

Size of feed, inches	Reduction ratio	Relative tons per hour
3 to 4	8.9	100
2 to 3	6.7	170
1 to 2	4.4	182
0.5 to 1	2.2	232
0.125 to 0.5	1.1	419

Reduction ratio may, of course, be varied either by changing feed size with the setting constant or by varying set while holding feed size constant. In either case there is, within limits, an inverse change in capacity. Hersam reports the results summarized in Table 6, for a crusher having a minimum throat opening of 0.24 in. and a throw of 0.21 in., crushing a uniform granite of various sizes, when the ratio is decreased by decrease in feed size. Table 1 shows the other case.

The reduction ton (T_R) is a unit in which the capacity of a crusher may be stated in such a way as to take into consideration both the tonnage of solid crushed and the extent of size reduction. As used throughout this book it is defined as

$$T_R = TR_{80} \qquad (8)$$

where T = tons crushed per hr. If the feed contains undersize, this should be deducted

from the stated feed rate in order to determine T. Such undersize must also be allowed for in evaluating R_{80} (see p. 10). The comparative reduction ton (T_{Rc}) is a modification of T_R, related thereto by the equation

$$T_{Rc} = T_R/K \tag{9}$$

in which K is a factor designed to reduce a specific value of T_R to a common comparative basis for which $K = 1$. This corresponds to uniform full-capacity feeding of dry thick-bedded medium-hard limestone, which is the basis upon which the published capacity representations of most crusher manufacturers are founded. K may be quantified for particular cases from the relationship

$$K = kk'k'' \tag{10}$$

in which k is the crushability factor (see Table 3), k' is the moisture factor (p. 12), and k'' is the feed factor (p. 12). A value of $k'' = 1.0$ requires almost the equivalent of hand feeding in such a way as to maintain a continuously full crushing zone. Careful feeding from a bin by a positive mechanical feeder, start-stop controlled by a good crusher tender, the feeder discharge passing over a grizzly and thence to the crusher, may be assigned a k'' value of 0.75 to 0.85.

Fig. 12 gives capacity on thick-bedded limestone, in terms of comparative reduction tons per hr., plotted against gape, for straight-element jaw crushers of Blake type having a ratio of length of receiving opening L to gape G of 1.5 : 1. For other ratios multiply T_{Rc} by the factor $L/1.5G$. This graph is based on Table 1. Comparison with values of T_R from Table 8, reduced to the same basis, shows a range of performance to the plotted values of T_{Rc} of 0.3 to 1.8, averaging 0.96. Not too great dependence is to be placed on the numerical average. The figures for T_R in Table 8 involve considerable estimate as to size of feed and product. No estimate of K was possible. It is known that low values of T_R in Table 8 corresponded in many cases to crushers where over-capacity was a result of reception demands, while some of the high values correspond to cases in which undersize was passed through the crusher in indeterminate amounts and credited to tonnage.

Fig. 12, taken with Eq. 9, may be used to estimate the size of standard Blake-type jaw crusher required for any given duty.

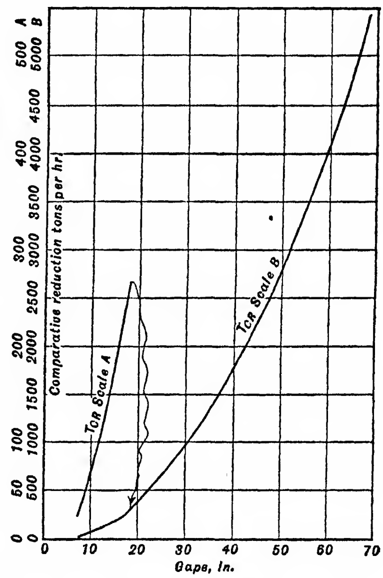

FIG. 12. Capacity of standard Blake jaw crushers.

Example: Assume that a crusher is wanted to break 50 t.p.h. of run-of-quarry granite that has passed through an 18-in. grizzly. It is desired to have a product that will pass a 4 1/2-in. grizzly.

The first step is to find a value for T_{Rc} in Eq. 9. Since the feed of the example is run-of-quarry granite, it may be taken to have a straight-line cumulative-direct square-mesh sizing curve, and since the shape factor is the same for feed and product, the percentage undersize will be $(4.5/18)100 = 25\%$. This leaves $0.75 \times 50 = 37.5$ t.p.h. to be crushed, which is the value for T in Eq. 8. However, since Fig. 12 is for dry limestone fed at maximum rates ($K = 1.0$), in order to apply the curve to the stated case, the corresponding value for K for this case must be found.

From Table 3 the value of k for granite is, say, 0.85. On the assumption that the undersize will be scalped out before feeding, $k' = 1.0$. If it is assumed that the crusher will be fed from a surge bin by a pan feeder with push-button control, k'' may be taken as 0.75. Hence $K = 0.85 \times 1.0 \times 0.75 = 0.64$.

Then, by Eqs. 5, 6, 7, $R_{80} = 1.7[0.8(18) + 0.2(4)]/1.4(4) = 4.6$ (assuming that the crusher must be set at 4 in. to have the product pass a 4 1/2-in. grizzly and that the shape factor for granite is 1.7).

Then $T_{Rc} = (37.5 \times 4.6)/0.64 = 270$.

A crusher to receive feed of 18-in. maximum thickness with a shape factor of 1.7 should have a gape of $18/0.85 = 21.2$ in. and a length of $1.7 \times 18 = 30.6$ in., both minimum, if sledging at the crusher is to be avoided. The nearest larger standard receiving opening is 24×36-in.

From Fig. 12, T_{Rc} for a 24×36-in. crusher is about 600. This crusher would have a capacity of $0.64(600 \div 4.6) = 83$ t.p.h. of scalped granite with a 4-in. open set against the desired capacity of 37.5 t.p.h., but the excess capacity is dictated by reception requirements. With some sledging a 24×30-in. crusher with a $T_{Rc} = (30 \times 600)/(1.5 \times 24) = 495$ could be used so far as reception is concerned. The value of k'' would, however, fall to, say, 0.5, making $K = 0.42$. T_{Rc} would then be 410. This is within the capacity (495 comparative reduction tons per hr.) of the 24×30-in. crusher.

A number of formulas giving capacity directly have been proposed. ***Hersam*** developed, from the theoretical ribbon, a formula for capacity of standard Blake crushers which reduced to

$$T = \frac{54t(2s_c + t)wfn\delta K \cdot 10^{-5}}{G - s_c}$$

or, since f = approximately $2G$,

$$T = \frac{108t(2s_c + t)wGn\delta K \cdot 10^{-5}}{G - s_c}$$

where T = t.p.h.; n = r.p.m.; s_c = distance between jaws at bottom, when closed (close setting); t = throw; f = vertical depth of jaws; G = distance between jaws at the top when closed (substantially = width of receiving opening, or GAPE); δ = sp. gr. of rock; K is a factor varying with changing operating conditions but averaging from Hersam's experiments on laboratory-size crushers about 0.75; and w = length of receiving opening. All dimensions are to be taken in inches.

Michaelson (*PC*) uses a formula that is based on the assumption that crusher capacity is expressible in terms of a constant times gravity flow of a theoretical ribbon of solid rock through the throat at open setting. Using the symbols defined above, for rock of average specific gravity (δ = 2.65), this formula is: $T_{\text{(theoretical)}} = 500w(s_c + t)/n$; and $T_{\text{(actual)}} = 500wK'(s_c + t)/n$. Michaelson states that, based on actual operation, K' varies for straight jaw plates, from 0.18 to 0.30, and for nonchoking curved plates, from 0.32 to 0.45, with screened feeds. He recommends that for estimating purposes, where average irregularities in feeding occur, the lower figures of the ranges should be used. For unsized feeds increase the results by formula about 25%. The apparent anomaly involved in the assertion of the formula that capacity decreases with increase of speed follows from the implicit assumption that crusher breaking capacity is always in excess of discharge capacity. Flow will decrease, of course, under such an assumption, with increase in the number of interruptions per unit of time, *i.e.*, with r.p.m.

Flow formula for capacity. A purely empirical relationship between tons per hr. T and maximum area of discharge opening is: $T = 0.6ws_o$, where s_o and w are the open setting of the crusher, and the length of receiving opening respectively, both in inches. For small crushers the answer will be high; for large crushers, low.

It will be noted that both the Michaelson and the flow formulas indicate proportional increase in capacity with increase in set, whereas Hersam's formula indicates a more than proportionate increase. The latter relationship accords the more closely with experience, particularly at the ends of the range.

Comparison of direct capacity formulas with performance figures from Table 8 shows that no one of the formulas is safe for more than approximate estimation. The Hersam formula with K = 0.75

Table 7. Deviations of Blake breaker capacity formulas

Formula	Hersam		Michaelson	Flow
	K = 0.75	K = 0.4	K' = 0.2	
No. of mills in which actual value exceeded calculated value	7	19	4	19
Percentage excess of actual:

Average of all deviations of calculated from actual, percentage basis	−70 *b*	+10 *c*	−75 *b*	+6 *c*

a Actual taken as percentage base.
b Calculated in excess of actual.
c Actual in excess of calculated.

and the Michaelson formula with K' = 0.2 appear very likely to give values nearly twice as great as those met with in actual operations, whereas the Hersam, with K = 0.4, and the flow formulas preponderate somewhat on the conservative side. It must be borne in mind, however, that primary crushers are rarely worked to anything like full rated capacity and that experience proves that actual capacities are usually well beyond rated except on very tough ores. Also, capacity goes up roughly in inverse proportion to reduction ratio. When these considerations are applied to Table 7, the conclusion

indicated would seem to be to use Hersam with $K = 0.75$ or Michaelson with $K' = 0.2$ for relatively easy crushing rock, with small reduction ratio, when no excess capacity need be provided for; otherwise use Hersam with $K = 0.4$ or the flow formula.

Performances as reported from the mills are presented in Table 8.

ah 5 lb. grease and 1 qt. black gear oil.

ai Nominal.

aj See p. 10.

ak Eq. 8.

Efficiency of crushing machines is customarily stated as hp-hr. (or kw-hr.) per ton of product, or as the inverse, tons of product per hp-hr. If, however, these units are investigated, as, for example, by examination of Table 1, it becomes apparent immediately that, if the table is in any way reliable with respect to production through different open settings, either the machine cannot be made to draw the same amounts of power with different settings—which is ridiculous on the face of it, since the energy transmission chain does not change—or the tons per hp-hr. must change with each change in setting, if the machine is constantly loaded to capacity and the power draft remains substantially constant. This latter is, of course, the fact. The work constant which corresponds to a constant energy input (power draft) at full load is the product of weight crushed by diametral reduction. This is the reduction ton. The comparative reduction tons per hr. for the various crushers of Table 1, with different settings, are substantially constant. REDUCTION TONS PER HP-HR. is obtained by dividing reduction tons per hr. by the hp. consumed. It is a reasonably true measure of the practical efficiency of the crusher in reducing limiting size, which is the function of primary and intermediate crushing machines.

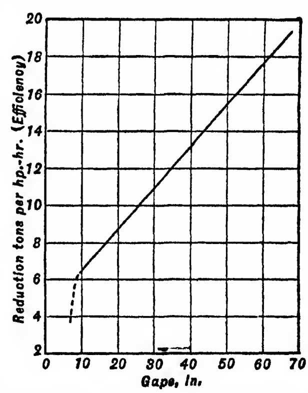

FIG. 13. Efficiency of standard Blake-type jaw crushers.

Efficiencies of jaw crushers increase with size of crusher, as is to be expected from the increases in mechanical advantage that occur with increase in size of machine. Performance data are not sufficiently complete to supply an accurate basis for reduction tons per hp-hr. for the various sizes. Fig. 13, plotted from Fig. 12 on the assumption that full-load power draft is 85% of installed horsepower, indicates efficiencies almost certainly too low for the machines larger than 18-in. gape, if they are worked through their full range of reduction ability. The figures in Table 8, on the other hand, are almost certainly too high for most of the crushers, since they are, in large measure, based on the assumption that the crushers are working through their full reduction range and that the reported feed rate is sufficient to keep them continuously busy. If the first assumption is untrue the crusher is credited with too much reduction, whereas if the second is erroneous not enough power is charged, since the crusher draws 50 to 70% of its full-load draft while idling (Fig. 5, and *99 J 399*). Both errors tend to cause the efficiencies calculated in Table 8 to be too high. The truth, for most crushers, probably lies between the values of Fig. 13 and those in Table 8.

Fall through the machine proper is about twice the gape. To this must be added the additional drop necessary to get feed to the machine and product away. If chutes are used, they may not safely be set at less than 45°.

CALUMET & HECLA (*100 J 11*) uses a special crusher with 3-ft. 6-in. fall for 24-in. gape and 4-in. set. This has been found a great aid in freeing the crusher when mass copper clogs the jaws.

Lost time. The average percentage of lost time in the mills due to causes chargeable to the jaw crushers themselves, such as repairs and renewals, clogging and its attendant difficulties, is less than 1%. Renewal of jaw and cheek plates and rebabbitting of bearings are the principal causes of lost time. When the crusher is planned to run one or two shifts per day only, as is done in a majority of mills, renewals and repairs are handled in the off shifts. In such cases substantially no delay is chargeable to the jaw crushers in most plants.

Attendance. The usual practice is a man to each machine. Rarely one man attends two machines. The principal duty of the attendant is to regulate the feed rate and to pick powder, steel, and waste. When the crusher is fed by dumping carloads or skip-loads of rock directly into the jaws no picking is possible, but the attendant must see that material does not bridge, or he must break up such jams as occur.

Crane service. See Sec. 20, Art. 12, for general discussion. Less than 50% of mills reporting had such service, but most large crushers are so served.

Feeding jaw crushers. Jaw crushers should be fed regularly and up to capacity, if possible. Maximum size of feed is theoretically a parallelopipedon of thickness (minimum dimension) slightly less than the gape, width slightly less than the length of receiving opening, and any length. Practically the particle thickness should not exceed 85% of the gape, and if its length is greater than the length of receiving opening, bridging is likely to occur, even with controlled feeding. Crushers may be buried when no feed particle is of greater length than the gape; otherwise burying may cause bridging; this necessitates laborious digging out in order to get the flow of rock started again. Some form of positive feeder with ready start-and-stop and speed control (Sec. 18) is an economy. Fig. 14 shows a power-actuated hook for removing lumps from between the crusher jaws. Tongs may be hung on the same power hook for lifting lumps clear of the crusher. Ample guard should be provided to prevent pieces of rock from dropping into the actuating mechanism, or serious accidents may occur.

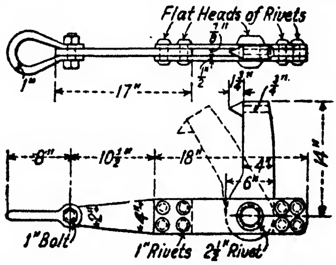

FIG. 14. Hook for jaw-crusher feeding.

Breaking point is provided in most coarse crushers to take care of excessive loads caused by introduction of material, such as metal, that cannot be handled. In Blake breakers the usual breaking point is one of the toggles (Fig. 3). Traylor builds a pitman in which the lifting force is applied to the rocker through a punch set in the pitman and a mild-steel punch-plate set over a die in the rocker. Excessive pressure causes the punch to perforate the plate whereupon, although the pitman continues to rise and fall, no motion or pressure is transmitted to the swing jaw. The device is reset by jacking up the toggles and moving the pitman until the punch-plate can be moved to a new position. In crushers not specially provided, the usual effect of a stoppage under full working load with power on is either to crush the babbitt of the pitman or to throw the belt or both. If the belt does not throw off and there is not a satisfactory overload circuit breaker on the driving motor, a burned-out motor will result. Most large modern installations provide an overload circuit breaker on the motor, which, in case of an overdraft of power due to clogging, cuts off the power and stops the motor.

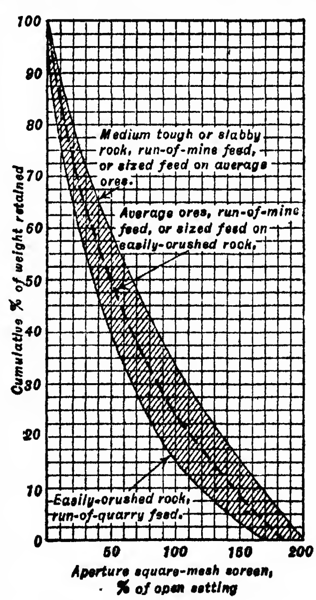

FIG. 15. Size distribution in jaw-crusher product.

Size of product varies somewhat according to the toughness of feed and to its sizing test. Operating data are not plentiful, but the best data available (*RI 3377, 3380, 3390;* Allis-Chalmers, *PC; CU*) indicate that the following rules are fairly dependable. The product of a crusher with straight jaw plates will all pass a square-mesh testing sieve of an aperture equal to 1.7 to 2 times the open setting; 65% to 85% of the product will pass a similar screen of aperture equal to the open setting, the lower percentage for tough or slabby rock, the higher for relatively friable rock that breaks granularly; about 40% of the product of a crusher fed with run-of-mine or run-of-quarry product approximating straight-line size distribution will pass a square-mesh testing sieve of aperture equal to half the open setting, this percentage falling to 25 to 35% with sized feed. The size showing maximum weight is always at or near the open setting. Fig. 15 is reasonably safe for estimates of size distribution in crusher product under the usual conditions there presented.

Shepard (*RI 3380*) found, in a careful test with a 60×84-in. crusher with an open setting of 7 1/2 in. on granite, 1.25% less <1/8-in. material was produced when the <6-in. material was screened out ahead

of the crusher than when the crusher was fed with run-of-quarry rock. Experience at COPPER RANGE (*95 J 947*) is that primary jaw-crusher product (<4-in.) is more even-sized if fines are not screened out ahead of the crusher, since slabs do not pass through so readily under this circumstance.

Operating cost of jaw crushers is best estimated from the data given on power consumption, attendance, and wear. These items make up about 90% of the total cost. For rough estimates, 8 to 10¢ per ton for small crushers to 2 to 3¢ for large are outside figures.

Horizontal-pitman crusher (Fig. 16) comprises the usual swing and fixed jaws in the usual positions in the main frame, but the drive shaft *B* actuating the short horizontal pitman *C* is carried near the base of the frame, and the pitman bears directly against the shimmed seat *D* in the lower end of the swing jaw. This construction lowers the height of the main frame and, together with the lessening of the reciprocating weight and of the eccentricity required for a given throw, should serve to decrease vibration. On the other hand, the force-multiplying effect of the usual toggle mechanism is lost so that much greater loads are brought onto the eccentric bearing itself. This crusher is run somewhat faster than the Blake type. It is made up to 15×24-in. size and at that size, for a given frame, metal and type of construction are somewhat lighter than the Blake.

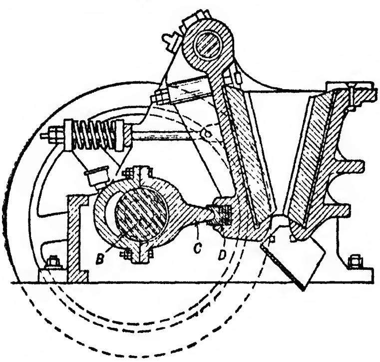

FIG. 16. Horizontal-pitman jaw crusher.

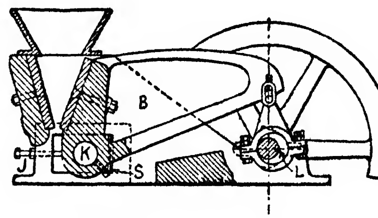

FIG. 17. Dodge jaw crusher.

Dodge breaker (Fig. 17) differs essentially from the Blake in that the movable jaw is pivoted at the bottom. In the original Dodge type shown in the figure the movable jaw was mounted on the short arm of a lever whose fulcrum was the swing-jaw shaft *K*, and the long arm *B* was actuated by an eccentric *L* on the drive shaft. Adjustment of the size of discharge was effected by shims *S*. In later designs toggles and pitman have been used to actuate the swing jaw, as in the Blake type; and the only difference between the two types becomes the essential and important one of the place at which the swing jaw is pivoted. Sizes and essential operating data of Dodge breakers are given in Table 9.

Table 9. Operating data for Dodge crushers

Size of receiving opening, in.	Weight, pounds	Capacity, tons per hour				Revolutions per minute	Horse-power
		Size, inch	Tons	Size, inches	Tons		
4×6	1,100	0.75	0.5	....	....	300	3
6×9	3,200	0.75	1.5 to 2.5	1.5	3 to 5	250 to 300	4 to 6
7×11	5,500	....	....	1.5	6 to 8	250 to 300	7
8×12	5,900	0.75	3 to 5	1.5	7 to 10	250 to 300	10
11×15	14,000	0.75	6 to 8	1.5	10 to 20	250 to 300	15

The Dodge breaker, owing to the manner of pivoting the swing jaw, is forced to do its greatest work at a point on the working end of the lever farthest from the fulcrum. This makes it most uneconomical in the use of power. The capacity is low as compared with that of the Blake by reason of the relatively small movement at the throat. It has the further disadvantage that there is difficulty in nipping the material being crushed and as a result lumps tend to fly out of the jaws. Sticky ores tend to clog it.

The Dodge-type breaker is made in smaller sizes than the Blake and is, therefore, suitable for small plants where power consumption is so low as to be unimportant and where fine size and uniformity of product are of distinct advantage. Attempts to operate with setting less than 3/4 in. will, however, usually result in mechanical trouble. Many of these crushers are sold sectionalized for small mills in isolated regions with difficult transport.

Single-toggle jaw crusher (Fig. 18) has the swing jaw hung on an eccentric *a* on the main drive shaft. The lower end of the swing jaw *b* rests against the single toggle *c*. The swing jaw thus receives two kinds of actuation, *viz.*, backward-and-forward and up-and-down from the continuous-wedge action of the eccentric, and a superimposed fore-and-back movement from the toggle.

In the machine pictured, with clockwise drive, starting with the long radius of the eccentric horizontal and to the right, the entire swing jaw starts downward and away from the fixed jaw. When the long

arm of the eccentric reaches a position substantially in the longitudinal axis of the swing jaw, the lower end of the latter has reached its position of maximum opening while the upper end is approaching the half-point of its backward motion. During this part (substantially one-quarter) of a revolution, no crushing is being done. From this point until the long arm reaches horizontal to the left, the lower part of the swing jaw is crushing and the upper part opening farther. Further rotation starts closure and crushing by the upper part of the jaw, at a slowly accelerating rate, and continues closure and crushing by the lower part, at a decelerating rate, until the long arm is again in the axis of the swing jaw, when approach and crushing in the lower zone cease. Further rotation now starts opening at the throat, as approach at the mouth passes through its maximum rate with the long arm vertically upward. From this point to the beginning of the cycle, approach at the mouth is at a decreasing rate and opening at the throat is accelerating for most of the time. Thus idle time is held to less than 1/5 revolution; the entire jaw is crushing during only about 1/5 of the time, and during this time not at a maximum rate over the whole jaw; while during the other 3/5 first one and then the other half only of the jaw is working. The effect is to shorten the period of maximum draft on the stored energy of the flywheels, tending to maintain speed and capacity and to decrease power consumption. Performances (see Table 11) confirm this analysis.

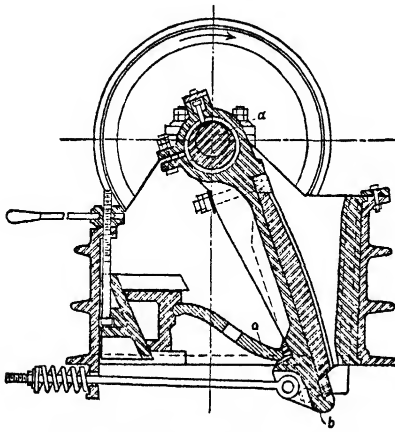

FIG. 18. Single-toggle jaw crusher.

The design of this crusher eliminates the pitman, with no corresponding increase in size or weight of the swing jaw. The crusher is limited in size, however, by the tremendous pressure imposed on the eccentric. This pressure increases, with an eccentric of fixed throw, with increase in horizontal motion at the throat. The eccentric is of roller-bearing type in the best crushers, but even with this construction 24×36-in. is the largest machine yet listed (1939).

When fitted with curved jaw plates, a 10×24-in. single-toggle crusher can be set to 1/4-in. minimum. In general, on screened nonslabby feeds, this type of crusher yields a product of which upward of 90% will pass a screen aperture equal to the open setting and 50% the closed setting. It is particularly useful either as an intermediate crusher or as a primary in a small plant working a one-step reduction to a reasonably fine ball-mill feed. By decreasing the angularity of the toggle with the horizontal (lowering the rear seat) the change in throat opening per revolution may be reduced to a minimum approaching the zero change of the Dodge, while still maintaining a lively movement tending to accelerate discharge.

Table 10, composited from manufacturers' catalogues, shows sizes available.

3. GYRATORY CRUSHERS

The gyratory crusher is a reciprocating pressure-type breaker, loading particles gradually, principally as short columns (occasional slabs are loaded as beams), and having unhindered gravity discharge. It consists essentially of a fixed crushing surface in the form of a frustum of an inverted cone around the axis of which gyrates a movable crushing surface, which has the shape of a conical frustum in erect position. The material to be broken is fed into the downward-converging annular space between these two crushing surfaces, it is crushed when the surfaces approach, and the crushed material falls through when they recede. It may be looked upon as a jaw crusher wound around a vertical axis through the midpoint of the swing-jaw shaft. The machine has been built in three types, known respectively as the suspended-spindle type, the supported-spindle type, and the fixed-spindle type. The first is the best known and most used; the second is fast disappearing in the old form, but new forms appear from time to time (see Art. 6); the third is relatively a newcomer.

Sizes of gyratory crushers as now sold are indicated by stating the gape of the receiving opening in inches. Total length of opening, measured along the outer rim, is approximately 8 to 10 times the gape in sizes below 26-in. and 6 1/2 to 7 1/2 times in the larger sizes. In the past, suspended- and supported-spindle crushers were rated by numbers with a letter suffix, *e.g.*, 7 1/2*K*. The suffix K indicated a suspended spindle, D a supported spindle; the numbers were roughly half the gape in inches.

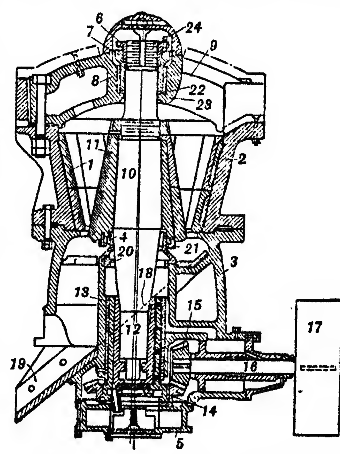

FIG. 19. Short-shaft suspended-spindle gyratory crusher.

Suspended-spindle gyratory is built in two forms, known respectively as the long-shaft and short-shaft types. The short-shaft machine (Fig. 19) is the modern form. It is characterized by the fact that the eccentric is situated above the bevel wheel. The main frame carrying the concaves *1* is made up of the upper shell *2* and the lower shell *3*, rigidly bolted together. The upper shell carries the concaves and the two-armed spider *9*. The spindle *10*, carrying the breaking head *11*, is suspended at its upper end from the spider. The lower end of the spindle passes through the eccentric sleeve *12*, which runs in a vertical bearing *13* cast integral in the lower shell. Rotation of the eccentric sleeve is accomplished by means of bevel gear *14*, bevel pinion *15*, shaft *16*, and pulley *17*, driven by some form of belt from the source of power. The axis of the spindle thus suspended and driven describes the surface of an acute cone, the apex of which is within the spider; the amplitude of the base is determined by the eccentricity of the sleeve *12*. At the same time, the spindle, being free to rotate around its own axis, rotates slowly—in the same direction as

the travel of the spindle when the crusher is empty, in the reverse direction when the crusher is working.

Rock to be crushed is fed into the converging space between the concaves and the breaking head. The pieces fall as far as their size allows, then seat against the crushing surfaces, where they are broken by the movement of the mantle toward the concaves. As the mantle recedes the fragments fall to a new seat and are again crushed as the mantle approaches the concaves at the point where they are resting. When material is finally broken so that it will pass the lowest annular space between the breaking head and concaves, it falls onto the annular sloping diaphragm *18* in the lower shell and discharges through spout *19*. Dust and grit are kept away from the gears and eccentric bearing by a dust seal comprising the cap *20*, bolted to the upward extension of the eccentric bearing, the dust collar *21* bolted to the under side of the mantle, and a packing ring *4*, unattached, which closes the gap between *20* and *21*. Similar arrangements designed to make a dustproof joint between the bottom of the breaking head and the top of the hollow central column are used in other makes (Fig. 20). The bottom plate *5* supports the weight of the eccentric and bevel wheel but takes none of the crushing strain. The eccentric is made of larger bearing area and is provided with a more elaborate lubrication system than was necessary in the older long-shaft machine (Fig. 21), in order to take care of the greater reaction pressures induced by shortening the power arm of the crushing lever. The shorter spindle decreases spindle breakage and lessens the clear height necessary above the machine. Access to the gear chamber is by removable doors in the bottom shell. Access to the eccentric bearing is gained by lowering the bottom plate.

Shell is built up of heavy castings which may be of iron, high-test iron, or cast steel. The joint between the upper and lower portions is a tapered fit and is heavily flanged. The bolt holes in these flanges are drilled in such a manner that the upper shell may be turned on the lower shell, if desired. The lower shell is heavily flanged at the bottom to form a base for supporting the crusher and for bolting to foundations. All parts of the shell that are subject to wear are lined with replaceable parts. The bottom shell should be so cast that the space between the bottom of the breaking head and concaves and the highest point of the diaphragm or annular chute is as large as possible, in order to prevent clogging by slabs of rock. Discharge chute on the opposite side from the drive, as shown in Fig. 19, is known as STANDARD ARRANGEMENT. RIGHT-ANGLE DISCHARGE, with the center line of the discharge chute in a plane at right angles to the axis of the driving shaft, is furnished if desired. With such discharge, a RIGHT-HAND CRUSHER is one in which the driving pulley is on the right when the discharge chute is faced; a LEFT-HAND CRUSHER is the reverse of this. Normally the hand must be specified, but in some makes the bottom shell is provided with seats for the countershaft bearing which permit change to any hand in the field.

Bottom plate in long-shaft crushers is made of cast iron, heavily ribbed, in order to furnish a strong and rigid bearing for the gear-driven eccentric sleeve. It is so bolted to the flange of the lower shell as to allow it to be dropped in the foundations by means of long threaded bolts depending from the lower half of the shell. A track is provided in the foundation on which the bottom plate may be slid out to one side after dropping, to facilitate work on the gear and eccentric.

Hopper or **spider rim** is made of cast iron or cast steel, heavily ribbed. In larger crushers it is sectionalized so that only the inner ring need be removed in order to allow removal of the spider. In most crushers the hopper is so arranged that it is not necessary to remove it in order to remove the concaves; in others the inner section of the hopper projects over the concaves, the argument for such construction being that it lessens bridging of rock above the crushing zone. In large crushers the hopper is lined, usually with cast-steel sectional plates.

Spider is made of cast iron in small crushers and of high-test cast iron or cast steel in the largest crushers. Since it carries the fulcrum of the crushing lever and is two-armed only, it must be very heavy and must be strongly fastened to the spider rim in order to prevent any weaving or breakage under lateral stresses. It should be so shaped that it forms an arch over the receiving opening of such height that the largest piece of rock that can enter the receiving opening can pass under it freely, if bridging and clogging of the crusher are to be prevented. In some crushers the base of the spider is a continuous ring forming the inner circle of the hopper. It has been claimed that such construction results in more breakage than when the spider is not an integral part of the hopper (*113 P 336*). Michaelson (*PC*) asserts that such failure is largely the after-result of casting strains and that by using an extra-heavy slow-cooled rim or by casting the rim split and thereafter fastening by shrink bolts before machining, the advantage of integral connection of spider to rim over a bolted connection may be obtained safely. The shorter spindle decreases spindle breakage and lessens the clear height necessary above the machine. Sometimes the spider arms are broadened out at the ends to give a large base for secure bolting to the upper shell. Spider arms should be protected by wearing shields unless the crusher is so fed that only occasional particles of rock come into contact with them.

Spindle or **main shaft** is the lever by means of which the crushing force transmitted through the eccentric bearing is applied to the rock. It must, therefore, be of great strength and capable of withstanding a continuous succession of shock loads. It is made in most crushers of hammered, open-hearth steel, specially heat-treated, turned, and polished. For extremely heavy work it may be made of special alloy steel. It is usually made to taper toward both ends, thus giving maximum cross-section and strength at the point of greatest stress. One maker hollow-bores the spindle in order to remove any defects or cracks due to the original forging that might work outward. Threads are cut at the upper end to accommodate the adjusting nut and also at a place near the upper end to accommodate the

nuts that lock the mantle. Key seats may be cut under the breaking head and adjusting nut, but usually the breaking head is held pressed down tightly on its taper by self-tightening head nuts similar to those used in tightening the mantle on the head (see p. 26).

Suspension bearing is of different detail in different makes of crushers, although of the same principle in all. The underlying idea is to bring the suspending surface as near to the point of no movement as possible. In the suspension bearing shown in Fig. 19 a split-steel nut (*6*) is turned to a downward taper on the outer surface and fits into the tapered upper portion of sleeve (*7*), which in turn is enclosed loosely within the spider bushing (*8*) and rests on the wearing ring (*22*), seated in the spider head (*23*). The weight of the spindle and breaking head and the downward pull thereon due to crushing clamp the split suspending nut (*6*) ever more tightly into the threads on the spindle. Jack nuts (*24*) are provided for backing away, after which the nut may be turned for vertical adjustment of the spindle. In one make of crusher the wearing ring is suspended on a nest of heavy springs so that the breaking head can be forced down by unbreakable material, with possible discharge thereof.

Eccentric sleeve transmits the crushing force to the lower end of the spindle. It therefore works under high pressures and should have as large a bearing surface as possible. In most makes the eccentric is babbitted inside and out with special hard babbitt; in one make, bronze bushings are substituted for babbitt. The inner surface of the central sleeve in the lower shell, which surrounds the eccentric sleeve, is bushed. The gear wheel is keyed or riveted to the eccentric sleeve. The eccentric sleeve rides on a wearing ring of brass, bronze, or steel. In most crushers the eccentric sleeve has cylindrical faces, but in one make the inner face is spherical and engages a spherical ball on the spindle. The argument in favor of this construction is that it is self-aligning and affords a greater area of contact than the cylindrical eccentric. A gear-type oil pump (Fig. 20) forces oil through passages as indicated by the arrows.

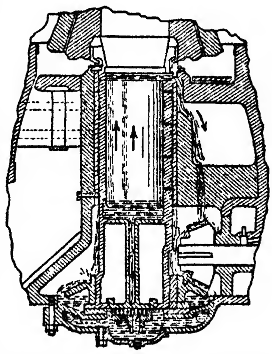

FIG. 20. Lubrication system for gyratory crusher.

Gears are made of cast or forced steel with cut teeth. Provision is made, by varying the thickness of the wearing rings or by adjustment of the countershaft bearing, for taking up a small amount of wear in gear and pinion. Fitting the main gear down over the head of the eccentric sleeve and keying it thereto would seem to be better construction than that in which the gear is riveted onto the eccentric.

One manufacturer makes a gearless crusher in which the usual gearing is replaced by a horizontal pulley or by a built-in vertical-type synchronous motor. This arrangement allows the spindle to be driven at a higher speed than with gears, which is an advantage in secondary-crushing service. (See p. 40.)

Countershaft bearing is made extra long and is cast as an integral part of the bottom shell or may be made adjustable in order to take up wear on gear and pinion. Modern practice inclines toward antifriction roller bearings. An outboard bearing of the usual ball-and-socket type is furnished, except where Tex-rope drive is used.

Drive pulley in older crushers was loose on the shaft and transmitted power through pins to an auxiliary hub keyed to the shaft. The purpose of this arrangement was to furnish a breaking point.

a Based on run-of-quarry limestone scalped to the open setting stated; crusher buried; straight-element mantles and concaves.

b Usual gear ratio is approximately 1 : 2.5.

Modern crusher construction, however, eliminates this feature and the driving pulley is made extra heavy, with clamped hub keyed onto the drive shaft. Small crushers are belted to transmit one horsepower per inch of belt traveling at 1,000 to 2,000 f.p.m., reckoned on installed horsepower; the corresponding figures for large crushers are 400 to 500 f.p.m. Tex-rope drive is common, and in some cases direct connection with the motor through flexible coupling is employed.

Discharge-chute design is a sore point with operators handling sticky ores, and with crusher builders faced with the necessity to keep the spindle short for strength and the fall through the machine low for economical mill design and operating economy. From the builder's point of view the high point on the chute should be crowded up as near as possible under the crushing head, but such design results in sticking and clogging with moist or clayey ores, owing to the small momentum which the discharged material striking at this point has attained after discharge from the crushing zone. The usual design expedients are: (1) a special inverted-vee saddle liner plate to give greater initial slope at this point; (2) a 2-way discharge chute, which permits dropping the chute diaphragm without lowering the chute lip, but produces separated discharge streams that usually must be brought together again with further loss of head; (3) elimination of the chute and substitution of a shield over the driving mechanism, around the entire periphery of which discharge takes place. A hopper must then be provided in the foundation to bring the discharge stream together, which interferes with free bottom access to the drive mechanism.

Sizes. Data as to the different sizes of short-shaft suspended-spindle gyratories available, compiled from the publications of the principal manufacturers, are given in Table 12.

Long-shaft suspended-spindle gyratories. Although the current offerings of large crusher manufacturers are of the short-shaft type, the majority of suspended-spindle gyratories now in use are predominantly of the long-shaft type, in which the eccentric is below the drive gear (Fig. 21). Essential structural difference from the short-shaft machine, other than in the location of the eccentric with respect to the bevel wheel, is that the eccentric bearing is carried in the bottom plate *a*, which constitutes a third principal element of the main frame. Data representative of sizes and performances of these machines, selected from typical manufacturers' ratings, are given in Table 13.

a Modern practice numbers the crusher by inches gape.

b Based on run-of-quarry limestone scalped to the open setting stated; crushers fitted with straight-element mantles and concaves.

Supported-spindle gyratory of the old type has not been built for a number of years. A recent crusher of this general type for fine-reduction service is described in Art. 6.

Fixed-spindle gyratory (Fig. 22) is best known under the name of TELSMITH BREAKER. It differs from the types already described in that spindle *a* is rigidly fixed top and bottom and the movement of the crushing head *b* is effected by an eccentric sleeve *c* running between the spindle and the crushing head itself. The mechanical principle is that of a continuous wedge. Discharge of rock is vertical; a discharge chute is no essential part of the crusher proper. Lubrication is effected by a pump *d* operating in an oil well *f*, oil being thus forced by pipes to all sliding surfaces. The frame and spider are made of cast steel and, as a result of this fact and the vertical shortening made possible by applying the moving force directly under the crushing head rather than at the end of a spindle acting as a lever (as in the other types of gyratory), the weight for a given size reduction and capacity are less than in the other types.

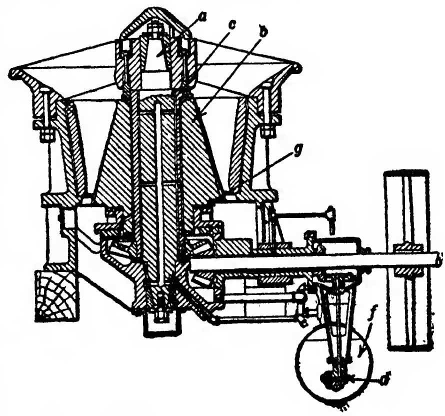

FIG. 22. Fixed-spindle gyratory crusher.

The fixed-spindle gyratory is used as a primary or secondary coarse crusher. Its relatively small height lends itself to rugged construction and the short spindle cuts down the clear height that must be left above the machine for convenience in repair work. The fact that the length of stroke is the same on both large and small pieces is an advantage when soft, tough material is being crushed but is unnecessary and may be disadvantageous with hard and brittle materials.

The sizes available and performances to be expected are given in Table 14, compiled from manufacturer's data.

Table 14. Data on fixed-spindle gyratory crushers, from manufacturer's catalogue

a Capacity based on run-of-quarry limestone scalped to the open setting stated. Crusher fitted with straight-element mantle and concaves.

Concaves for gyratory crushers are made almost without exception of manganese steel, very occasionally of chilled iron for light service. (Compare right and left sides of Fig. 19.) The staves are wedge-shaped, supported either at the bottom by a sectional removable iron rim resting on a shelf on the lower shell or by means of lugs or ribs that are cast on the back near the top and fit into a groove in the top shell. After being set in place the staves are backed by hard zinc or hard babbitt poured in between them and the shell. Frequently the lower edge of the staves is beveled in order to increase the amount of metal behind the point at which maximum crushing is done. Staves are usually sectionalized into two, three, or four tiers, according to the size of the crusher. At some plants the upper tiers are made of chilled iron and the lower of manganese steel.

WEAR of concaves varies according to the material used. Figures from practice are given in Table 15.

Breaking head is, like the concaves, made either of chilled iron or manganese steel. Chilled-iron breaking heads are solid and fastened directly to the spindle. When manganese steel is used, a soft iron or semi-steel core is fastened to the spindle and a mantle of manganese steel is slipped on over this. (See Fig. 19.) In small crushers the head is keyed to the spindle with zinc or babbitt or steel; in large

crushers a self-tightening nut of the general type shown in Fig. 24 is used to press the head tightly onto a tapered spindle. The mantle is held down on the core by another self-tightening arrangement. Two devices are commonly used. GUN-LOCK MANTLE is illustrated in Fig. 23. In the form shown the core is keyed to the spindle by means of feathers in keyways *a*. On the outside of the core two grooves *b* are cut at 180°, and the bottom of the core is finished to a curve whose highest point is at the bottom of grooves *b*. The mantle is ground to fit closely on the head and is cast with lugs *c* that slip down the grooves *b* and pull the mantle tightly onto the core as the mantle turns with respect to the spindle. Another SELF-TIGHTENING MANTLE is shown in Fig. 24. In one form the nut is made of three pieces: piece *1*, pinned to the top of the mantle and carrying on its inner surface a left-hand thread; piece *2* having a corresponding left-hand thread on the outside to engage piece *1* and a right-hand thread on the inside to engage the thread on the spindle; and piece *3* with a right-hand thread inside. When the mantle loosens it works round on the core and imparts its motion to nut *1*. If the direction of motion is such as to cause the left-hand thread to unscrew, the mantle is thereby pressed down onto the core. If, on the other hand, the motion is such as to cause the left-hand thread to tighten, then nut *2* is caused to move down on the spindle, again pressing the mantle down on the core. With this type of mantle zinc is used to make a tight joint between the mantle and the core. A DISADVANTAGE of the use of self-tightening locknuts is that large pieces of ore jammed in the mouth of the breaker may loosen the control nut. This happened frequently on a primary gyratory at MOOSE MOUNTAIN (*99 J 973*).

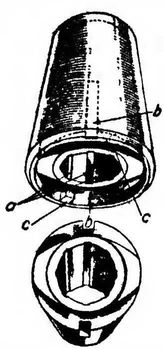

FIG. 23. Gun-lock mantle for gyratory crusher.

FIG. 24. Self-tightening locknut for gyratory mantle.

In large crushers the mantles are frequently made in two parts. The greatest wear comes at the bottom, and the amount of metal that must be wasted can be decreased by making the bottom part replaceable while retaining the old upper part. Mantles are made corrugated or smooth. The corrugated head is best for coarse breaking; a smooth head is best if a large proportion of fines is desired or if the feed to the crusher is already relatively fine. LIFE of mantles is given in Table 15.

Bell-head fittings (Fig. 25) comprise the combination of concave mantle and convex fixed breaking surface for a gyratory corresponding to the curved breaking faces for a jaw crusher (see Fig. 8 and discussion). Traylor Eng. & Mfg. Co. reports (*PC, 3/3/42*) that about 300 standard gyratory crushers have been refitted with the curved fittings. The advantages are the same as with the jaw crusher.

Lubrication. In all crushers the eccentric bearing runs submerged in oil. Capillarity is depended upon in some crushers to draw oil from the bath into the bearing surfaces while in others a forced feed is used. A pump drives the oil upward along the spindle bearing into an upper well whence it feeds by gravity over the outer surface of the eccentric and bevel gear faces and also through the countershaft bearing back to the well. Some makers provide coils for cooling water in the oil reservoir. One form of forced feed, using a gear pump attached to and driven by the eccentric, is shown in Fig. 20. In small crushers the main countershaft bearing is ring- or chain-oiled with overflow from the reservoir into an oil sump in the bottom plate. It is probable that the best lubricating system is one in which an efficient forced feed of heavy oil is employed. Extrusion of this oil around bearings aids to keep grit and dust out.

Manufacturers of gyratory crushers: Allis-Chalmers Mfg. Co., Eimco Corp., Gruendler Crusher & Pulverizer Co., Kennedy-Van Saun Mfg. & Eng. Corp., Morse Bros. Mach. Co., Smith Eng. Wks., Sturtevant Mill Co., Traylor Eng. & Mfg. Co.

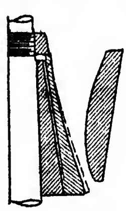

FIG. 25. Bell-head fittings for standard gyratory crusher.

Adjustments of gyratory crushers are (*a*) width of discharge opening, (*b*) throw, and (*c*) speed. Width of discharge opening is changed in the suspended-spindle crusher by raising or lowering the spindle by means of the adjusting nut (6), Fig. 19. A ring bolt is furnished to engage the top of the spindle, which is then hoisted by appropriate means, allowing the adjusting nut to be readily moved as desired. In the fixed-spindle type the adjustment is made by changing the thickness of shims (*g*), Fig. 22. Range of adjustment in width of opening is limited because of the fact that the nip angle is markedly increased as a result of wear of the breaking head. This increase in nip angle causes a great decrease in ability of the crusher to discharge, with corresponding decrease in capacity. If more than a small adjustment in width of discharge is required, it must be obtained by using thicker and shorter concaves and breaking head.

Throw is less than in jaw crushers. It is adjustable only by changing the eccentric sleeves. It should be greater in large crushers than in small and should be greater for relatively soft and tough rocks than for hard and brittle rocks.

Speed may be varied throughout wide limits. Increased speed is not accompanied by the marked increase in vibration and shock that occurs with jaw crushers. The lowest speed compatible with the capacity required is most economical within certain operating limits. A tendency to clog by reason of the sticky character of ores may often be overcome by increase in speed, thus increasing the sharpness with which the head recedes from the concaves.

a Numbers in italic refer to Table 15*a*.
b Gape + open setting.
c Eq. 5.
d 5 men.
e 180 for CI; 450 to 540 for steel.
f 300 for upper half; 90 to 120 for lower half.
g Increased about 50 days by use of oversize head.
h 3 sizes of mantles used in sequence; 1 set of concaves lasts as long as 3 mantles.
i 570,000 tons, mantles; 460,000 tons, concaves.
j Aver. bowl-liner tonnage 518,022.
k Upper, CI; lower, Mn.
l Scalped to 2.5 in.
m Grizzly bars.
n Estimated.
o 592,000 tons.
p 5,050,000 tons.
q Built up as soon as flanged, usually after 150,000 to 200,000 tons; built-up sections have 1/3 to 1/2 life of new mantle. Start with 45-in. diam. mantles and finish with 49-in. on each set of concaves.
r 1,157,000 tons.
s Scalped on 10-in. grizzly.
t Babbitt every 1,000 days.
u No appreciable wear in 10 yr.
v Tons per hr. $\times R_{80}$ (Eq. 8).
w Manganese.
x See Eq. 1.
y See Eq. 3.
z On the assumption that "maximum," referring to feed, designates the spacing of the limiting grizzly.
aa Estimated at $1.16G$ on basis that thickness t of largest particle is $0.85G$, w for this particle is F_s $(=1.7)t$, and $w_{80} = 0.8w$ on basis of straight-line size distribution.
ab Estimated from setting on basis that $w_{80p} = 0.6F_s s_e = s_e$ when $F_s = 1.7$.
ac Nominal.
Hf = Hard-faced; hard-surfaced.

Speed, throw, capacity, reduction ratio, and power consumption are closely related. If the reduction ratio is increased when the crusher is working near maximum capacity, the speed of the crusher must be increased to keep up the capacity. This will be accompanied by a considerable increase in power consumption. If the machine is sufficiently overmotored so that the change brings no perceptible strain on the driving equipment, it is well to watch for heating of the eccentric, as any marked increase in the direction above noted over the figures recommended by the manufacturers is likely to result in burned-out bearings. If increase in reduction ratio without change in shape of the breaking zone is to be effected without mechanical troubles, it should be accompanied normally by decrease in speed and a decrease in the amount of material in the crushing zone, brought about by decrease in feed rate. (But see Art. 6.)

Performances are given in Tables 15 and 16.

Size of feed is governed by the same considerations as apply to jaw crushers (see p. 09).

Reduction ratio, estimated on 80% basis, at 20 plants reporting, ranged from 3.3 to 11.6 for primary suspended-spindle crushers and averaged 6.8. Corresponding figures for fixed-spindle machines are: 11 plants, range 3.9 to 9.1, average 6.1. These figures involve, however, so many estimates as to render them indicative only and probably consistently high. Manufacturer's recommendations for the ratio of gape to minimum open setting for machines with straight-element mantle and concaves range from 6 to 9 with increasing gape, while with maximum settings the corresponding range is from 3 to 6. Primary-type machines with curved concaves will operate at considerably larger ratios.

Michaelson (*PC*) reports a 20-in. machine, fed with rock as coarse as it will take, reducing to 93% <1.5-in. and 72% <1-in. at a power consumption slightly more than 1 hp-hr. per ton (T_R per hp-hr. = 21) and a 15-in. machine reducing 12-in. feed to 90% <1-in. at a consumption of approximately 0.9 hp-hr. per ton (T_R per hp-hr. = 16.3).

Angle of nip in gyratory crushers with straight-element crushing surfaces ranges from 21° to 24° with an average near 22°. On large primary gyratories, where gravity is of marked aid to nip with the large pieces at the mouth, and with curved surfaces, the angle runs up to 27° to 30°.

Capacity. For general discussion, see p. 11. Capacities for different sized crushers, according to makers' catalogues, are given in Tables 12, 13, and 14.

The Hersam capacity formula is supposed to be applicable to gyratory crushers as well as jaw crushers, but when applied with $K = 0.75$ to the performances listed in Table 15 percentage deviations range from +90 to −670, while with $K = 0.4$ the range is from +94 to −390. The range for the flow formula is nearly as great and the Michaelson formula is entirely inapplicable.

Comparative reduction tons per hr. for suspended-spindle machines, as calculated from manufacturers' ratings, are given in Figs. 26 and 27, and those for the fixed-spindle machine in Fig. 28. The hatched areas represent the range in rating as it develops from the variation in tonnage recommendations for different settings of the same crusher. Since there is no reason to believe that the maximum capacity of a given machine to crush a given feed has different values, it follows that a line should represent this maximum capacity, and such lines, which smooth out and average the manufacturers' statements of capacity, have been run in on the charts. These lines are recommended for use in estimation (see p. 13).

a Numbers in italic refer to columns in Table 15*a*.
b Gape ÷ set.
c See Eq. 4.
d Estimated.
e Life: Mantle 105,000 tons; concaves 70,000 tons.
f Upper ring chilled cast iron, lower manganese steel.
g Rubber being tried.
h Causes not connected with crusher.
i Very hard rock.
j With one set of concaves; used another 90 days with another set of concaves.
k Old ball-mill liners.
l Babbitt inner liner 100 operating days, outer liner after 150 operating days.
m 1/4-in. sheet iron.
n Babbitt liners every 180 days.
o See Eq. 1.
p See Eq. 3.
q On the assumption that "maximum," referring to feed, designates the spacing of the limiting grizzly.
r Calculated on basis that $w_{80f} = 0.80 \times 0.85GF_s = 1.16G$ (see p. 10).
s Calculated on basis that $w_{80f} = 0.80 \times 1.7 \times \text{max.} = 1.36$ max. (see p. 10).
t See Eq. 4.
u Taken as equal to s_e on basis that this determines $t_{\max}$ and that $w_{80p} = 0.6F_s t_{\max}$ (factor 0.6 from Fig. 33).
v On basis $w_{80} = 0.6w_{\max}$ (see Fig. 33).
w On basis that limiting $t_f = 0.85G$, and/or limiting $t_p = s_e$, and $w_f = t_f F_s$.
x These data are derived on assumptions which tend generally to give maxima. Exceptionally high figures should be viewed with extreme doubt.

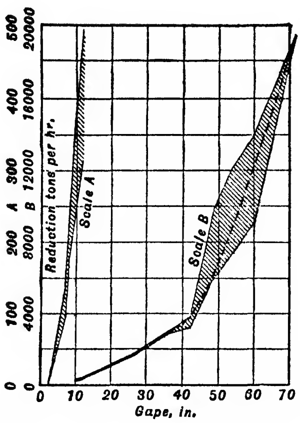

FIG. 26. Capacities of short-shaft suspended-spindle gyratory crushers (*Makers' ratings*).

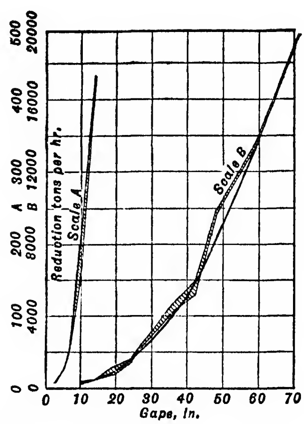

FIG. 27. Capacities of long-shaft suspended-spindle gyratory crushers (*Makers' ratings*).

Capacities reported from the field range from 0.3 to 2.31 times the values from the dotted curve, the average for 17 reports being 0.88. Two out of three field crushers show low capacities, the discrepancy being greater, in general, with large crushers. The reason for this is, probably, that the crushers are oversize to satisfy reception requirements. Reported field performances greatly in excess of rated capacities are, so far as can be judged, usually due to crediting the crusher with undersize present in the feed. This is not necessarily inconsistent with Shepard's findings (*RI 3377, 3380*) that the number of tons of rock finer than either the open setting or half thereof produced per 100 tons of feed is from 1.5 to 2 times greater with sized feed than with unsized feed, while the time required for a choke-fed crusher to free itself of a skip-load of sized stone is no greater than is required for a skip-load of unsized stone. It is not believed that the high performances reported are due to exceptionally easily crushed rock, for the reason that there is no consistent correspondence of this kind indicated.

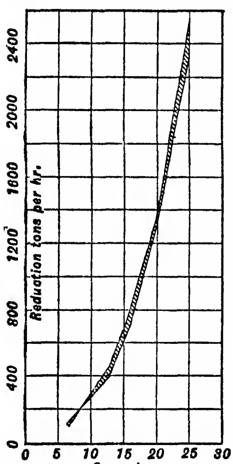

FIG. 28. Capacity of fixed-spindle gyratory crusher.

Power. Motors should have ratings well in excess of average or even of full-load power drafts to take care of cold starting and to carry over feed rushes without serious loss of speed. Minimum recommendations of the manufacturers, as shown in Fig. 29, are nearly twice average full-load drafts.

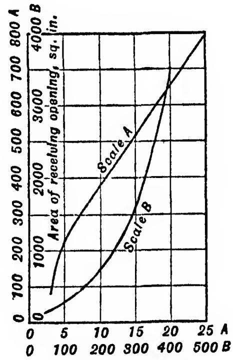

FIG. 29. Installed horsepower for long-shaft suspended-spindle gyratory.

Figs. 30 and 31 represent the results of power tests on gyratory crushers in actual operation. The figures show that idling power is roughly 30% of the full-load peak.

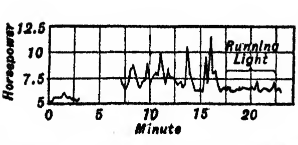

FIG. 30. Load curve of 6-K Gates gyratory crusher.

Notes to Fig. 31. Speed of pinion shaft, 207 r.p.m.; maximum size of feed, 24-in.; largest particle in product, 4-in.; rate of feed during test, 99.6 t.p.h.; average hp., 26.2 (decrease chart readings by 2.7 hp. for power draft of a conveyor driven by the same motor).

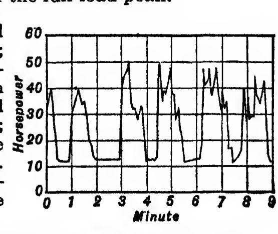

FIG. 31. Load curve of No. 8 Gates gyratory crusher.

Efficiency of primary gyratory crushers, based on estimates from the performances reported in Tables 15 and 16, are shown in Fig. 32. These figures are not to be taken too seriously on account of approximations that were necessary in calculation, owing to lack of sizing tests, and of integrated readings of energy consumption. The effect of underloading is clearly shown.

Fall through machine proper is about 10 times the gape for machines up to 12-in. gape. For larger machines the figure decreases with increase in gape from 8 to 6. Closer figures for fall are given in Tables 12, 13, and 14. These figures will come within a few inches of the exact ones for crushers made by any of the leading manufacturers.

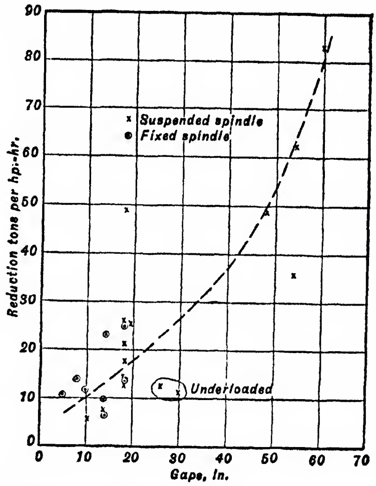

FIG. 32. Efficiencies of primary gyratory crushers; straight-element crushing surfaces.

Lost time. Average percentage of lost time in the mills due to causes chargeable to the crushers themselves, such as repairs and renewals, clogging and its attendant difficulties, is less than 1%. Renewal of mantles, concaves, and chute liners and rebabbitting of the eccentric bearing are the principal causes stated. One plant reported 8% lost time due to clogged chutes. In this plant a 12-in. crusher was discharging a product, a considerable proportion of which was more than 4 in. in size; an extremely large tonnage was being put through, and clogging was to be expected unless a large drop was allowed from the concaves to the highest point of the diaphragm. The majority of the crushers reported are planned to work but one or two shifts per 24 hr., thus leaving at least one shift free for all minor repairs. With good planning and with a sufficient supply of repair parts on hand, such operation will practically eliminate lost time.

Attendance. Usual practice is one man per machine to two or three machines per man. Where the gyratory crusher is the primary machine there should be an attendant for each machine to remove waste. Where the gyratory is a secondary crusher little or no actual attendance, apart from oiling and watching for trouble, is necessary.

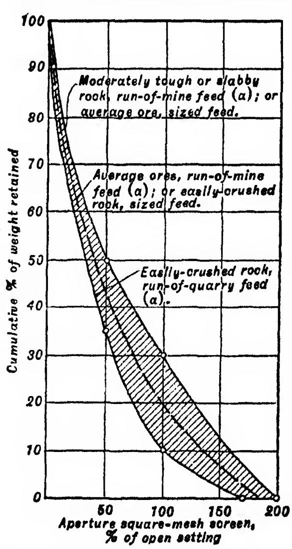

FIG. 33. Size distribution of gyratory-crusher product.

Crane service. See Sec. 20, Art. 12, for general discussion. A majority of the mills reporting had crane service to the gyratory crushers. Such service is universal for large machines.

Feeding. The crusher should be fed regularly and as nearly as possible up to capacity. Maximum capacities will be attained when the feed rate is completely and readily controllable, as is possible with some form of positive movable feeding surface with effective start-and-stop and speed controls. (See Sec. 18, Art. 22.) If the feed contains particles near the largest that can be received, it is wise not to bury the crusher, as bridging may easily occur and necessitate digging aside a lot of heavy material. However, bridging is much less likely to occur in gyratory crushers than in jaw crushers and many more of the former are fed so as to be buried. The majority of plants report the crushers fed by chutes or over stationary grizzlies. Other methods reported are by belt or pan conveyors, drum feeders, and shaking or vibrating grizzlies and chutes. Pan conveyors are probably the most satisfactory method for feeding initial crushers. Most of the chute-fed crushers occupy a secondary position in the mills, taking feed from a primary crusher.

Breaking point is not generally provided in modern gyratory breakers. The big breakers will pass almost any piece of steel that gets to them, without stalling or breakage. Small crushers will generally slip a belt before breaking, and, if the motor is properly safeguarded against overload, this is a fairly satisfactory method of procedure. In older crushers a breaking pin was provided in the driving pulley. Overload circuit

breakers are probably the best method of providing against damage with machines directly connected to a motor.

Size of product of primary gyratory with head and concaves having straight generating elements is dependent upon the breaking characteristics of the rock and upon the sizing analysis of the feed. Study of the rather sparse data available (*RI 3377, 3380; A-C, PC*) indicates that with nonslabby feeds all of the product will pass a square-mesh testing sieve of aperture equal 1.7 to 2.2 times the open setting of the crusher; 70% to 90% will pass a similar screen of aperture equal to the open setting; and from 35% to 50% will pass a similar screen of aperture equal to half the open settings. The higher percentages in both cases correspond to unsized, relatively friable feeds that break granularly. The size showing maximum weight is at or slightly greater than the open setting. Fig. 33 is reasonably safe for purposes of estimate.

4. COMPARISON OF JAW AND GYRATORY CRUSHERS

The bases of comparison for primary crushers are first cost, power and maintenance, on a capacity basis; operating labor will show no sensible difference except where the choice is between two primary jaw crushers and one primary gyratory, when the usual requirement of a tender on each primary machine will enter to the disadvantage of the jaw. Fig. 34 (*Courtesy Allis-Chalmers*) indicates the capacity basis for differences.

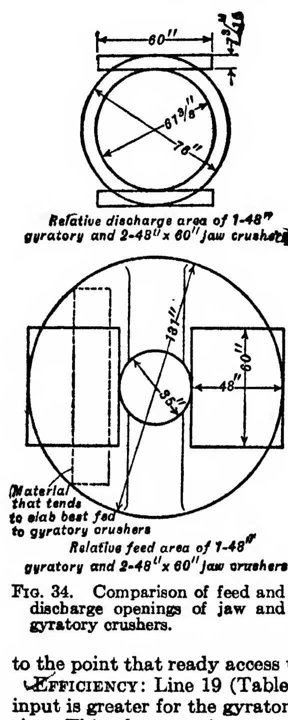

FIG. 34. Comparison of feed and discharge openings of jaw and gyratory crushers.

The elements of FIRST COST are the price of the machine itself and the costs of installation and housing. Table 17, which compares machines of average weights, shows, in line 13, that the gyratory costs, in general, from 29 to 7[illegible]% of the jaw per ton of hourly crushing capacity through a given reduction range, when both crushers are worked to capacity and machines of the same gape are available. INSTALLATION COSTS are substantially proportionate to the weights of the machines, but the gyratory, because of lesser tendency toward vibration, requires less costly foundations when installed high above the ground. HOUSING costs more for the gyratory on account of the requirement of much greater clear headroom above it to permit lifting out the spindle for replacing mantles; the gyratory also requires more vertical height below to permit dropping the bottom plate and removing gears and eccentric. What these excess requirements may amount to in dollars is a matter of individual design and estimate in each case and cannot be generalized. FEEDING ARRANGEMENTS will usually be simpler and easier to make with the gyratory, owing both to the fact that it can be fed from all sides and that the absence of mechanism at the top permits the crusher to be buried under the feed load, if desired, while the relatively great length of receiving opening gives better access of material to the crushing zone in case of bridging, so that the crusher clears itself to the point that ready access to the offending lumps is had with little or no manual labor.

EFFICIENCY: Line 19 (Table 17) shows that the size reduction done per unit of energy input is greater for the gyratory at all feed sizes, increasing generally with increase in feed size. This advantage is greater at underloads than at full loads. This flows from the fact, demonstrated by the work at WITHERBEE SHERMAN. Figs. 5, 30, and 31, that the POWER CONSUMPTION of a jaw crusher idling is roughly 45 to 50% of that at full load, whereas for the gyratory the corresponding figure is 30%.

MAINTENANCE is higher for the gyratory, both as respects material and labor. Gyratory crushing surfaces are not as readily sectionalized as jaw and cannot ordinarily be reversed, so that, even though the actual wear per ton crushed is probably not greatly different in the two types of machine, the rejections weigh more for the gyratory. Labor costs for changing the crushing surfaces in the gyratory will run several times those for the jaw. Eccentric-bearing and spindle wear in the gyratory are higher than the wear of corresponding surfaces in the jaw crusher because of the greater pressures under which these surfaces work, and the allowable wear before serious loss in crushing efficiency occurs is less with the gyratory.

CHARACTER OF FEED: The jaw crusher, since it is capable of a larger throw than a gyratory, is, when so adjusted, the better adapted to handle clayey and spongy rocks. (But with such feeds the single-roll crusher (see Art. 5) or the hammer mill (Art. 9) should be investigated.) Slippery rock that tends to jump out of the crusher when the crushing force is applied is best handled in a jaw crusher, simply as a matter of design, since the larger gyratories are usually built with nip angles 4 to 6° larger than jaw crushers of corresponding gapes. Because of the very great force which the toggle mechanism can transmit, the jaw crusher can be built to handle certain extremely hard artificial products, such as ferrotungsten and other ferroalloys. The jaw crusher is capable of more ADJUSTMENT OF SET without serious structural changes than the gyratory, and likewise may be somewhat adjusted as to THROW without change of eccentric, which is substantially impossible with the gyratory. The jaw permits, therefore, more flexibility in primary crushing to adapt to changes in feed and to alter the burden on the secondary crushers. LUBRICATION is better on the gyratory

If any general rule governing CHOICE may be enunciated, it is that for handling quantities of primary feed that are within the capacity of one jaw crusher, when the gape requirements would necessitate a gyratory of considerable excess capacity, and when future expansion of capacity is not a factor in the problem, a jaw crusher is probably the better choice. Practice is roughly summarized in the rule: If the hourly tonnage to be crushed divided by the square of the gape in inches is less than 0.115, use a jaw crusher; otherwise, a gyratory. On the other hand, the table indicates that for feeds in the range 24 to 36 in. thickness the prices of jaw and gyratory are substantially the same, while the gyratory has more than double the capacity of the jaw, and, even if run at the jaw capacity and charged with the correspondingly large amount of idling energy, relative reduction tons per hp-hr. for the gyratory will be about 1.8 times that of the jaw.

With an ore, the bulk of which is too hard for single-roll or hammer mills, but which contains such a large amount of clayey material that it clogs a jaw or gyratory breaker despite the usual expedient of flushing, preliminary washing in blade mills or wash trommels (see Sec. 10) is desirable. If the material is too coarse for such machines, a primary crusher, probably of the jaw type, with a wide set and a large throw, may be used to crush the undesirable oversize after separation on a grizzly; whereupon the crushed material recombined with the grizzly undersize may be washed prior to further reduction. At GETCHELL MINE drying was adopted with a very clayey ore.

Shepard (*RI 3380*) found, in a comparative test of jaw and gyratory crushers set at 7 1/2-in. and 5 3/8-in. open setting respectively, that the gyratory product contained less material larger than the open setting, and less fines, with correspondingly higher percentages at and near the size of the crusher setting, despite the fact that the mean reduction ratio was greater in the gyratory. Shepard's tests also indicate no difference between the crushers as regards shape of the product particles, departure from the equidimensional particle increasing both ways from a size near the crusher setting, and being greater the greater the reduction ratio in the crushing operation.

5. SLEDGING ROLLS

Sledging rolls (not to be confused with crushing rolls, Art. 8) are machines in which one (single-roll crusher) or two massive rolls (giant rolls, slugger rolls), armed with heavy projecting knobs or teeth, and set horizontally, break rock fed onto them by spalling and pinching.

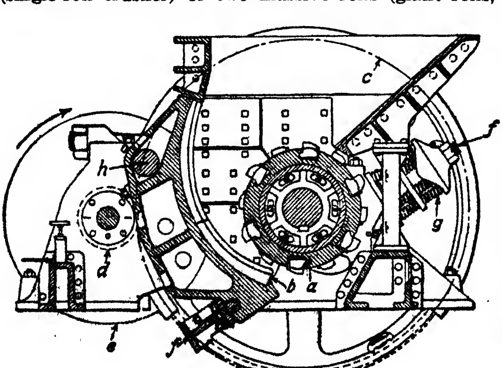

FIG. 35. Single-roll crusher.

Single-roll crusher (Fig. 35) consists essentially of the single toothed roll *a* and the stationary breaking plate *b*. The roll is driven by gear *c* and pinion *d* by means of a belt and drive pulley *e*. The breaking plate, hinged on *h*, is held in position by two heavy bolts *f*, one on each side, with a nest of compression springs *g* under the upper nuts to permit the plate to move away when an unbreakable substance is fed. Machines are built with roll diameters 18-in. to 60-in. and lengths from 1 1/2 to 3 times the diameter

and are operated at peripheral speeds of 200 to 300 f.p.m. The feed hopper of the large machines will take shovel-size rock.

Drive is normally by belt to an extra-heavy flywheel-type pulley from a motor, and thence through single-reduction gearing to the roll. Encased gears running in oil and direct connected to a motor through flexible coupling are available.

Wearing parts are made of chilled iron or manganese steel. Roll shells are made segmental with teeth cast integral, or entire with either integral or separate bolted alloy-steel teeth. Unless wear is excessive the entire shell with integral teeth is most satisfactory, as it eliminates trouble with loose teeth and also difficulty with rusted holding bolts. Teeth may be built up by hard facing. Compensation for partial wear is made by shimming up the breaker plate.

Frame is made of ribbed cast-steel sections, with accurately surfaced joints and strongly bolted. Bearings for all shafts are massive, are cast integral with the side sections, bushed with bronze, and designed to take up end thrust.

Breaking principle. The larger lumps are broken by the spalling action of the heavy teeth striking projecting parts of the lumps in contact with the roll surface. This action may be accentuated by making the teeth of different heights. Smaller lumps in the convergent zone between roll and anvil plate are sheared by the teeth and compressed to failure between the crushing surfaces. Positive agitation of the material in the crushing zone by the action of the teeth facilitates sifting through of fines and tends to decrease compacting and choking.

The machine will free itself if fed in surges, but the roll teeth tend to wear badly under the overlying load, and it is better practice not to bury it, but to use some form of regulating feeder.

Manufacturers. Allis-Chalmers Mfg. Co., Austin-Western Road Mach. Co., Bartlett & Snow Co., Dixie Mach. Co., Gruendler Crusher & Pulverizer Co., Jeffrey Mfg. Co., Kennedy-Van Saun Mfg. & Eng. Corp., Link-Belt Co., McLanahan & Stone Corp., Pennsylvania Crusher Co., Raymond Pulverizer Co., Stephens-Adamson Mfg. Co., United Iron Wks., Vulcan-Iron Wks.

Field. Single-roll crushers are particularly adapted to primary breaking of the large class of substances of which the medium and soft limestones, phosphate rocks, shales and other nonabrasive sedimentary deposits, slates, hard clays, and the like are representative. They operate best on thinly stratified rocks. The forced discharge is definitely helpful with sticky clays. They are superior to either jaw or gyratory crushers for wet or frozen slippery materials, provided these are not too tough or abrasive. They should not be used for abrasive material or when the crushing resistance exceeds about 15,000 lb. per sq. in.

Capacity varies tremendously with size of feed and its nature and with the crusher setting. The range is from 50 to 1,500 t.p.h. Stone too large to be nipped between roll and anvil plate may ride the roll for a considerable time before it is spalled down to a size that will nip, and a collection of such pieces has the substantial effect of a choke-up in the receiving hopper.

Table 18, compiled from data supplied by one manufacturer, gives figures for estimate. The following per-

formance data indicate that the manufacturer's figures are safe as to tonnages and rather conservative as to motor recommendations.

Performances on several different rocks are given in Table 18*A*.

At MALVERN CLAY Co. (*IC 6962*) an 18×30-in. roll driven 40 r.p.m. by a 30-hp. motor crushed 100 t.p.h. of hard clay to a maximum size of 4 in. At CLAY CITY PIPE Co. (*IC 6913*) a similar roll driven 50 r.p.m. by a 25-hp. motor crushed 60 t.p.h. of flinty clay to 6-in. maximum size. At CAMP BROS. Co. (*IC 6889*) a 24×42-in. roll driven 245 f.p.m. peripheral speed by a 40-hp. motor crushed 90 t.p.h. of hard clay to 6-in. maximum size. At VICTOR PLASTER, INC. (*IC 6967*) a 21×40-in. roll set at 1 1/4 in. and driven at 50 r.p.m. by a 75-hp. motor crushed 60 t.p.h. of interbedded shale, gypsum, and limestone. A 60×84-in. machine crushing limestone at MICHIGAN ALKALI Co., driven 23 r.p.m. by a 400-hp. motor and set for a 7-in. product, crushed 700 t.p.h. of 4×7-ft.-maximum shovel rock. *Miller* rates a 36×60-in. machine set for 6 to 8-in. limestone at 350 t.p.h.

c Taken as 60% of limiting size when limiting size only is given. See Fig. 35*A*.
d See Eq. 5. *e* Estimated.

Size of product. Shepard and Witherow (*RI 3377*) found that all of the product of a single-roll crusher breaking limestone passed a square-mesh testing screen with an aperture equal twice the crusher setting, 20 to 25% remained on a square-mesh testing screen equal the setting, and 30 to 40% passed a testing screen of half the setting, the coarser product with sized feeds. Reduction ratio (80%) with run-of-quarry feed was about 3.3 and was about the same as in a gyratory handling the same feeds. With softer feeds Table 18*A* indicates reduction ratios much larger, ranging from 6 with cement rock to 53 for bituminous coal. Characteristic sizing curve of product is given in Fig. 35*A*.

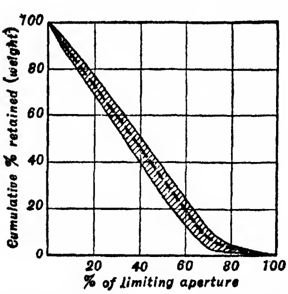

FIG. 35*A*. Characteristic product of single-roll crusher.

Power consumption. *Miller* states that power draft, while fluctuating, shows overloads of short duration and magnitude rarely exceeding twice the mean. Table 18*A* shows idling power to range from 17 to 42% of loaded power and loaded power equal to 40 to 65% of full-load power. Reduction tons per hp-hr. are much larger than with jaw and gyratory, owing, of course, to the much softer rocks crushed.

Giant rolls (slugging rolls) consist essentially of a pair of massive knobbed cylinders, similar to the single-roll, mounted on a massive frame with shafts parallel and in a horizontal plane. They are driven toward each other at the top. The projecting teeth strike spalling blows on lumps riding in the inter-roll vee, and also serve to decrease the nip angle (see Art. 8) and thus bring about seizure of lumps that would not be nipped by smooth-surfaced rolls of the same diameter and set. Roll diameters range from 3 ft. to 6 ft. and

lengths up to 5 ft., so that they can take almost any shovel rock. They are set to discharge at 4 to 8 in., according to the size of feed. Practice as to speed, with the resulting limitations imposed on the drive, results in two distinct types of machine. Slow-speed sledgers, driven 12 to 20 r.p.m., depend primarily on nipping and compression for their crushing action. All of the teeth project a relatively great distance from the roll face, to the point of actual intermeshing in certain cases, and are so arranged always that a longitudinal row of teeth on one roll face registers with untoothed surface on the other roll in the plane of the shafts. Such registry necessitates gear interlocking of the two rolls, while the slow speed requires further gear reduction from the driving pulley to the roll shaft. High-speed giant rolls are driven at 3,000 to 3,500 f.p.m. peripheral speed, usually by separate motors belted to heavy flywheel-type pulleys. Two rows of teeth at 180° on one roll project well beyond the other teeth and act as sledges to crack or quickly spall down large lumps to a size that can be nipped.

Construction is massive throughout. SHAFTS are high-carbon or alloy steels, of large diameter; bearings are of generous proportions, with forced lubrication; SIDE FRAMES are heavily ribbed castings of high-test iron or steel, or are fabricated of heavy rolled shapes and plates. The BEARINGS of one or both rolls are slideable in the frames. They are spaced by shimming. Crushing stresses are taken up by heavy steel TIE RODS, running completely through the frame lengthwise on each side, both above and below the bearings, in some makes buttressed against nests of compression-type SPRINGS. CORES are cast-iron cylinders, sectioned transversely, shrunk onto the shaft. SHELLS are usually chilled iron or manganese-steel segments, cast with integral teeth, with lugs or machined tongues fitting into corresponding depressions in the core surfaces, which are suitably flattened to receive the shell segments.

Performance. Slow-speed rolls are used principally in Germany, crushing limestone for cement manufacture and fluxing stone. *Miller* states that a 5×5-ft. machine will break 200 to 300 t.p.h. of shovel-size stone to <10-in. with a consumption of 150 to 200 hp. High-speed giant rolls were introduced by Edison into a number of cement plants and into a few ore-milling plants in the United States but are not now used in any of the latter, nor in few, if any, of the former. Recent installations are reported *(136 Eng 436)* for sticky, slippery relatively friable iron ores in England. A 60×54-in. machine crushed 400 t.p.h. of such rock from <48-in. to <8-in. with a power draft of 100 to 150 hp. per roll (200 to 300 hp. total). The manufacturer estimates that a 72×60-in. machine will crush 450 to 1,000 t.p.h. of such rock from 54×48×36-in. maximum to <8-in.

Size of product. *Miller* gives curves which indicate that approximately 10% of the product of high-speed rolls is coarser than the nominal set and that the average size distribution up to this point is substantially straight-line, limestone crushing somewhat finer than ironstone.

INTERMEDIATE CRUSHING

INTERMEDIATE (or SECONDARY) CRUSHING comprises the series of steps in the usual comminution process that intervenes between primary crushing and grinding. In some operations, *e.g.*, production of crushed stone or domestic anthracite, secondary crushing is the final stage in comminution; very occasionally secondary crushing and final grinding constitute one and the same step. Primary-crusher discharge will vary from, say, 3-in. up to 10- or 12-in. maximum, according to the mining method and the tonnage; grinding-mill feeds will vary from, say, 1-in. to 10-m. maximum, according to the judgment of designers as to the significance of the data available on the comparative economies of crushing and grinding over the range from 1-in. to 10-m. Hence the ratio of reduction to be effected in intermediate crushing may range in the extreme from 3 : 1 to 150 : 1; the number of stages ranges from one for the small ratio to as many as five or six for the large; the most usual number of stages in flotation and cyanide mills is two; gravity-concentration mills normally use more.

Principles. The desiderata in intermediate crushing are: (*a*) maximum economic reduction ratio per stage, in order to reduce fall, number of machines, amount of material transport, floor space, and building cubage; (*b*) large unit capacity per machine, which has much the same advantages as *a;* (*c*) low energy consumption; (*d*) low recurrent maintenance cost; and (*e*) reasonably high continuity of operation. The essential specifications of a machine to satisfy these demands are: a receiving opening large enough to take feed easily, with no tendency to choke or clog, lacking continuous attendance; a nonchoking crushing zone with sufficient retention of material therein to insure reasonable size reduction before discharge; a discharge passage of as large an area as is consistent with the size reduction demanded; as great a force as possible working to facilitate movement of material through the crushing zone and discharge of the crushed material; adequate crushing force and adequate area over which to apply it, with as nearly continuous application as possible; an efficient mechanism for converting rotary driving force to rectilinear crushing force; relatively high speed of application of crushing force; an efficient lubricating system, including cooling, if necessary; low wear of crushing surfaces and such design thereof that

replacement is infrequent and convenient to make; sufficient strength to withstand strains induced by accidental introduction of uncrushable material or a stalling load, and means for promptly freeing such material from the crushing zone; sufficient weight to prevent harmful vibration. It is usually essential in the final stage, and it is desirable in preceding stages, that the discharged product have a substantially uniform maximum size; failure in this respect may, however, be compensated by a separate sizing device.

Types of crushers. Machines now used in secondary service are gradual-pressure machines and impact machines. In the first class are the gyrators and rolls; in the second the hammer mills and stamps. Fast-running open-end rod mills of large diameter (Sec. 5, Art. 7) are also employed for the final stage in some well-designed plants.

The GYRATORS include the so-called reduction gyratories, cones, Gyraspheres, and disk crushers. One or another of these (excluding the disk, which is substantially obsolete) is found in the first intermediate stage in well upward of 90% of all hard-rock crushing plants. The cone predominates. Rolls and short-head cones predominate in the final intermediate stage in such plants, rolls being favored when the final product is relatively fine, cones when it is on the coarse side. Hammer mills are widely used for softer rocks. Stamps, when they are found today, have some very special reason behind their use, such as mass copper in the Michigan mills or the fact that they were installed before the development of modern fine-grinding equipment in the older cyanide plants, and could be converted to intermediate crushers serving tube mills, when these were installed, more cheaply than modern intermediate crushers could be put in.

6. REDUCTION-GYRATORY CRUSHER

The modern form of reduction gyratory should not be confused with the short-head modification of the standard gyratory that preceded it. The present machine, which is made in a variety of forms, constitutes a creditable attempt to satisfy the desiderata set up in the immediately preceding introductory paragraphs. It has the tested and proved frame and essential mechanism of the primary suspended-spindle gyratory. In order to maintain capacity in the face of the reduction in width of discharge opening necessarily incident to finer crushing, the convergent crushing zone is flared downward, thus increasing the length of discharge opening; speed is increased, thereby increasing the number of crushing impulses per unit area of crushing surface per unit time; concaves are curved, and the mantle may or may not have a curved face, thus gaining the nonchoking advantage explained in Art. 2; and, as an important incident to the combination of slowly convergent fine crush-

[a] S = short throw; L = long throw; M = medium throw.

ing zone thus obtained and the higher speed, which insures two or more pinches of particles at substantially the closed setting, it may be given a greater throw than can the slower-moving primary type, thus increasing the discharge area, without undue increase in maximum size of product.

Standard (coarse) machine. Fig. 36 shows a typical machine of the reduction type for settings down to $^3/_8$-in. and products of $< {^3/_4}$- or 1-in. limiting size. The machine involves minimum departure from the structure of the primary-type gyratory. The frame, suspension, and driving mechanism are of the usual suspended-spindle short-shaft type (Art. 3), except that the discharge diaphragm is omitted. Belt, Tex-rope, or flexible direct-connected drives are available. One manufacturer (*131 J 330*) suspends the spindle-supporting nut on one end of a heavy simple lever, with fulcrum on one side of the shell, and the other end of the lever held down by an adjusting screw backed by heavy springs. Highly desirable provision is thus made for protection against overload and tramp iron and for adjustment of setting during operation.

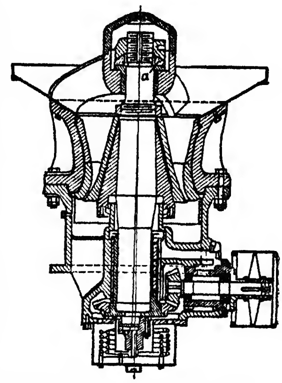

Fig. 36. Standard (coarse) reduction-gyratory crusher.

Size rating is in terms of the diameter of the head at the discharge point; the range in available sizes is 20-in. to 7-ft. The effective gape varies with a given size of machine according to the head and concaves with which it is fitted; it varies from about $^1/_7$ to $^1/_5$ the head diameter for fine bowls and $^1/_6$ to $^1/_3$ for coarse bowls. Eccentric throw will be varied by the manufacturer on a balance between the requirements for capacity and the limiting size for a given closed setting. Speeds are much higher than in standard gyratories. Estimating data are given in Table 19.

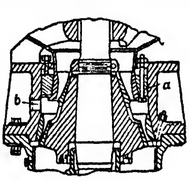

Fig. 37. Crushing zone of Traylor-Stearns multistage reduction gyratory.

Fine-reduction gyratory is on the market in two forms. One comprises essentially the mechanism of Fig. 36, but the breaking head is divided into an upper and a lower crushing section (Fig. 37) by a depressed section, and the concaves are in two vertically separated parts; the effect of this construction is to provide two distinct crushing zones, respectively coarse- and fine-crushing. Provision is made, by means of the suspended

from manufacturers' catalogues

backing ring *a*, to vary the setting of the upper crushing zone in such a way as to equalize the crushing duty between upper and lower zones. Hand-holes *b* permit observation of the intermediate feed zone. Provision is made to drop the spindle sufficiently, in case of a jam, to free the crushing zone; incidental access to the intermediate zone is possible through the hand-holes. The manufacturer gives test figures indicating a product with limiting size equal upward of 2 times the closed setting, and power and tonnage figures corresponding to 3 to 4.5 reduction tons per hp-hr. on trap rock.

Another fine-reduction machine is also of short-shaft type, but the spindle is bottom-supported on the upper end of a piston set in a cylinder bolted to the lower shell. Oil, pumped in through a branched valved pipe, serves to lift the spindle and breaking head to the desired setting; an automatic release valve on the cylinder acts as relief for choking overloads or when uncrushable material enters; manual release is supplied for intentional back-off. The breaking head is conical but more widely flared than in the standard reduction machine; concaves are curved. Throws are $^7/_{16}$-in. in the smaller machines with fine settings and range up to $^7/_8$-in. in the larger machines used for $^7/_8$-in. minimum set.

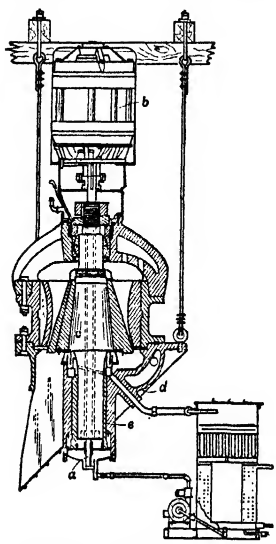

Fig. 38. Newhouse crusher.

Newhouse crusher (Fig. 38) is a high-speed short-shaft suspended-spindle gyratory with straight-faced head and curved concaves. Power is applied to the eccentric *e* by means of a shaft *a* which is, essentially, an extension of the rotor of the driving motor *b* through a tubular spindle *c*. The preferred mounting is by means of cables, as shown, which absorb the vibration incident to the high speed of gyration. The discharge diaphragm *d* is preferably omitted with sticky ores. Speeds are 500 to 600 r.p.m. with an eccentric throw of about $^1/_4$ in. For a given effective gape the machine runs from 10 to 15% lighter than the gear-driven reduction gyratory. Rated capacities and reduction tons per hp-hr. fall within the ranges given in Table 19; performance data available do likewise.

Gearless reduction gyratory has the characteristic curved crushing surfaces of the typical reduction machine but is of long-shaft suspended-spindle type and is driven by either a horizontal pulley or a built-in vertical-type slow-speed synchronous motor positioned on the lower end of the spindle. The spindle is hung from the suspension-bearing nut by a nest of heavy springs which relieves excessive load on the machine incident to the entry of unbreakable material.

Fixed-spindle type of gyratory is also modified for fine-reduction service. It is not recommended by the maker for as fine settings as the suspended-spindle machines of corresponding gape and weight, nor are the stated capacities to a given setting as large. The direction of motion of the head does not give favorable load application in the strongly flared bowl.

Manufacturers. Allis-Chalmers Mfg. Co., Kennedy-Van Saun Mfg. & Eng. Corp., Smith Eng. Wks., Traylor Eng. & Mfg. Co.

Structural data for reduction gyratories correspond, in general, to those already given for standard primary machines, *i.e.*, cast-steel shells and spiders, forged high-carbon or alloy-steel shafts, chilled-iron or manganese-steel wearing surfaces, and forced circulation of oil through channels in the eccentric bearing, gear housing, etc., from and to a reservoir fitted with a cooling coil.

One manufacturer makes the upper section of the shell reversible so that the concaves, zinced in place therein, may be reversed without dismounting.

Performance data for reduction gyratories are not available in sufficient number for reliable generalization, but on the basis of 10 to 20 incomplete reports for the smaller machines of several types, the reduction tons per hr. fall reasonably close to the averages in Table 19; reduction tons per hp-hr. are somewhat lower than the averages estimated in Table 19. Table 19*a* is based on reports from Traylor Eng. & Mfg. Co.

Size of product. Reduction gyratories in typical fine-reduction service, *i.e.*, with fine bowls and closed settings of $^1/_2$ in. or less make products all of which will pass square-mesh screens of aperture equal to 2 to 3 times the closed setting; 50 to 60% of the product is finer than the closed setting; and 15 to 35% is finer than half the closed setting. In coarse intermediate service the product tends to be more like that of the primary gyratory. In the usual types throw has relatively little effect on product size, if speed is in the range recommended. But the Newhouse crusher, which operates normally at higher speeds and with

[a] Estimated at 60% of limiting size for long-range feeds, and at 80% of limiting size for short-range sized feeds, on basis of Figs. 15 and 33.

smaller throws, may yield as high as 80% finer than the closed setting, with a limiting size slightly less than twice the closed setting.

Capacity is much greater per unit of discharge area than that of primary gyratories because of high speed and the relatively large throw and correspondingly large ratio between open and closed discharge areas. The high speed and large throw cause the breaking head to act to accelerate travel of material in much the way that a shaking conveyor acts, while the greater the difference between closed and open settings, the more unhindered the outflow of broken material when the head recedes. The fact that this difference decreases for a given machine as the setting increases, and becomes relatively small at the larger settings, explains the apparent anomaly in maker's ratings, according to which tonnage increases more slowly than the increase in setting, and the reduction tons per hour for a given machine are definitely lower at the larger settings.

7. CONE-TYPE CRUSHERS

The cone-type crusher (Fig. 39) differs from the gyratory as modified for fine reduction (Art. 6) in two important particulars: (1) The breaking head of the cone-type crusher flares much more rapidly, the depth of head being only about one-third its diameter at the base; (2) the throw of the head for a given closed setting ranges from 5 to 9 times the setting as against about 1 : 1 in the standard reduction gyratory. There are also two important differences in mechanism. The head is supported on a spherical bearing, and its eccentric is much longer than that of the gyratory, with the result that pressures per unit of sliding surface are substantially lower.

The difference in shape of head gives the cone-type machine greater discharge area for a given gape and setting than is found in the modified gyratory, and it makes the volume of the fine-crushing zone larger, relative to the volume of the coarse-crushing zone; the large throw causes the passage for the crushed material to be suddenly greatly enlarged, which permits the mass to become loose and fluid and thus to flow readily, and this loosening is accelerated by the fact that the receding head on the opening stroke drops away from under the mass of rock, permitting a short free trajectory as in a shaking launder. The result of these two aids to travel is faster movement through the crushing zone. At the same time the speed of the head is high enough to pinch all particles at least twice during their passage through the fine-crushing zone, so that discharge size is still determined by the fine setting.

Standard cone is shown in Fig. 39. The main frame comprises a cylindrical shell *a* within which and supported therefrom by suitable heavy fins cast integral is another cylindrical casting or hub *b*, which in turn supports socket *c*, fastened thereto by capscrews, and the bearing for eccentric *d*. The socket has a hemispherical bronze liner *e* on which the conical breaking head *f* rests. Shaft *g* is pressed into the breaking head and is supported by it. The tapered lower end of the shaft is bushed onto the long large-surfaced eccentric *d* which is driven through gear *h* and pinion *i* from countershaft *j*. This is, in turn, belt driven or flexibly coupled to a motor. The weight of the gears and eccentric only is carried through an eccentric-thrust bearing *k*, consisting of alternate disks of bronze and hardened steel, by the cap *l* bolted to the bottom of the hub. Bowl *m* is a cylindrical casting threaded, with coarse power threads, into adjustment ring *n* which rests on the main frame and is held down by bolts *o* passing through springs *p* nested, at proper tension, between a segmented spring ring *q* and a rim *r* around the top of the main-frame shell. This arrangement causes crushing stresses on the bowl to be transmitted to the frame through ring *n*, bolts *o*, segments *q* and springs *p*, which latter are adjusted to such a tension that, while normal crushing loads produce no appreciable compression, excessive loads cause compression and permit the adjustment ring *n*, and with it the bowl, to rise with the lift of the breaking head and thus relieve the strain.

a Feed is taken to have maximum thickness $t_{LF} = 60\%$ of crusher gape G, which tends to insure nonclog feeding. With average nonslabby ore, the limiting-screen aperture, w_{LF}, for such material $= 1.7t_{LF}$, and for primary-crusher product w_{80F} may be taken as 80% of w_{LF} or $w_{80F} = 0.8 \times 1.7 \times 0.6G = 0.82G$.

Limiting aperture of product, $w_{LP} = 2.2 \times$ closed setting s_c (see Fig. 42), and $w_{80F} = 0.62w_{LP} = 0.62 \times 2.2s_c = 1.4s_c$.

Power consumption (HP_c) is taken as 60% of recommended motor horsepower, on the basis of the averages of Table 22, the lower value for the range being taken for fine bowl and the upper for coarse bowl; for medium bowls the mean of the range was taken. $T_R = Tw_{80F}/w_{80P}$; $E_c = T_R/HP_c$.

b From Table 22.

The bowl may be turned, if desired, during operation of the crusher, after loosening cap-screw *s*, by suitable manipulation of windlass *t*, thus adjusting the setting. Bowl liners *v* of chilled iron or manganese steel are made in one piece and suspended from the bowl frame against zinc backing by bolts *u*. Mantle *w* of the same materials, similarly backed, is held down on the head by sleeve *x* and nut *y*, which is locked by plug *z*. A feed plate *A* carried on top of the spindle and a feed hopper *B* supported on the bowl distribute feed to the crushing zone. A suitable dust-sealing system is provided on the under side of the head. Oil is circulated by pump from a cooling sump upward through the eccentric bearing and through channels *C* to the socket bearing and thence by gravity over the gears and through the countershaft bearing back to the reservoir.

Sizes of standard cones are designated as the approximate diameter of the discharge annulus. Maximum size of material receivable is determined by the convexity of the bowl, the gape *G* (Fig. 39) ranging as shown in Table 20 according to whether the bowl is fine, medium, or coarse.

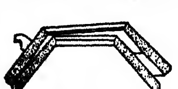

Fig. 40. Coarse bowl for short-head cone crusher.

Short-head cone has essentially the same frame and mechanism as the standard cone, differing in shape of crushing zone (Fig. 40) and having a somewhat smaller throw.

Sizes of short-head cones are designated on the same basis as those of standard cones (see above); coarse and fine bowls are available, as in Table 21.

Table 21. Estimating data for short-head cone crushers a

Size	Gape, in.	Capacities in tons per hr. (T), reduction tons per hr. (T_R), and efficiencies in reduction tons per hp-hr. (E_C), when closed set in inches is as below, a															Motor recommended, hp.	R.p.m.	Weight, lb.	Performances b

a Feed is taken to have maximum thickness $t_{LF} = 60\%$ of crusher gape G, which tends to insure nonclog feeding. With average nonslabby ore, the limiting-screen aperture (w_{LF}) for such material $= 1.7t_{LF}$. When the feed is standard-cone product, w_{80F} may be taken as $0.62w_{LF} = 0.63G$.

Limiting aperture of product w_{LP} is taken as 2.9 times closed setting, on the basis of Table 22, and $w_{80P} = 0.62w_{LP} = 0.62 \times 2.9s_c = 1.8s_c$.

Power consumption HP_c is taken as 75% of recommended motor horsepower on the basis of averages from Table 22.

$$T_R = Tw_{80F}/w_{80P}; \quad E_c = T_R/HP_c$$

b From Table 22.

bh Probably too high.

Gyrasphere crusher (Fig. 41) is of the cone-crusher type, but the crushing head *a* is a spherical segment, and its motion is effected through a combination of the actions of the gear-driven eccentric *b* and spindle *c*, and the cam ring *d*, on which the rollers *e* act as followers. Cam ring *d* is fastened to and revolves with eccentric *b* and is so formed that a vertical plane through its lowest element also contains the thickest vertical section of the eccentric sleeve. Thus the crushing load is exerted in part through the action of a lever comprising the spindle as the power arm, the rollers on the low part of the cam as fulcrum, and that part of the head opposite thereto as the working arm, and in part through the wedge action of the cam acting through the rollers on the high side. Tremendous pressures are, therefore, concentrated on the rollers and their race rings, and are transmitted to the frame through the lower roller thrust bearing (*f*); these become, in consequence, the crucial points in the mechanism. The machine has the same general type of vertical screw adjustment of the position of the bowl and of spring backing for the bowl as is found in the cone crusher.

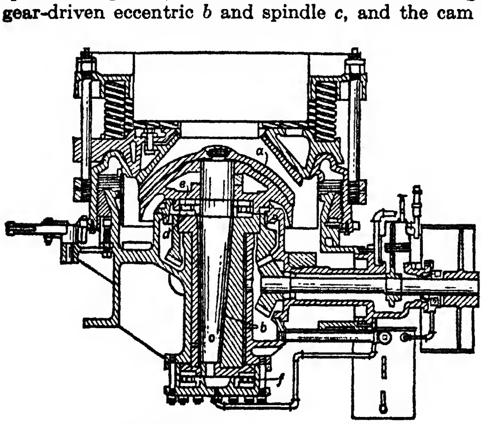

FIG. 41. Gyrasphere crusher.

Manufacturers of cone-type crushers: Nordberg Mfg. Co., Smith Eng. Wks.

Performance data are presented in Table 22.

a Blake-crusher product, 4-in. set. *b* Same as 8P. *c* Includes undersize of scalping screen.

Adjustment of the cone crusher is substantially limited to change in the discharge setting. The large eccentricity with the corresponding large throw (as much as 5 times that for the gyratory) is an essential part of the high capacity of the machine; it cannot be decreased without serious sacrifice of capacity, nor can it be materially increased without substantial redesign to take care of increased stresses. Speeds close to those recommended by the manufacturer and closely regulated are desirable, if maximum capacity and a uniform-sized product are to be attained. Change of setting is so readily effected, even with the machine under load, that it is advisable to make a predetermined drop of the bowl every 2 or 3 days to compensate for bowl and mantle wear. Care must be maintained, however, to reseat the adjustment capscrews firmly after all such changes, as a loose bowl will probably entail a costly repair job on the bowl-adjusting thread.

Feed to cone-type crushers should be of such maximum size as to enter the crushing zone readily and seat one or two diameters below the mouth; it should be free of material finer than the crusher set, else it will tend to reduce capacity by overloading and choking the fine zone; and it should be so fed as to distribute it on entry uniformly around the entire receiving opening. Barring bridging due to excessive coarseness, machines may be buried with feed and so run; one manufacturer recommends such practice.

Closed-circuit operation of short-head fine-bowl machines with vibrating screens is being used increasingly. It tends, however, to load up the circuit with material of a size near the crusher setting, which in turn has much of the choking effect of fines in the feed. Notwithstanding this tendency, operations are reported indicating economy in 2-stage cone crushing, with the circuit closed on the second cone with a 1/4-in. screen, as opposed to a 2-stage cone-rolls flow with the circuit similarly closed on the rolls.

Size of product. Substantially all of the product of a standard cone crusher working on nonslabby material will pass a square-mesh testing screen of aperture equal 1.5 to 3.0 times the set, average of 20 = 2.2 times. The percentage of product coarser than the set

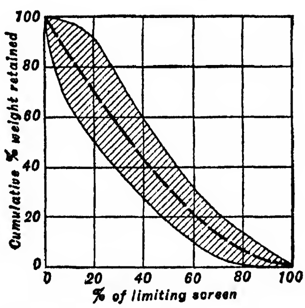

FIG. 42. Size of product of standard cone crusher.

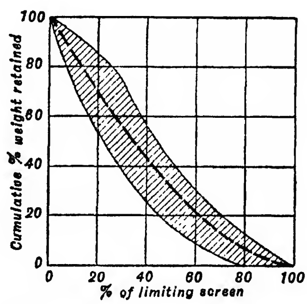

FIG. 43. Size of product of short-head cone crusher.

ranges from 14 to 70, being greater, in general, with the coarser settings; average of 17 reports was 32. Performance data indicate a clustering of values around 25 to 35% coarser than the setting, but the manufacturers in rating their machines tend to estimate 40 to 50% coarser for coarse bowls and 25 to 30% coarser for fine bowls. The percentage that will pass a screen of aperture equal to half the setting ranges from 13 to 55% (average of 17 was 38) with a clustering of values around 35 to 45%; again the manufacturers run to the conservative side, estimating 35 to 40% for fine bowls but dropping to 25 to 30% for coarse bowls.

For short-head cones the ratio of limiting-screen size of product to set averages 2.9, with a range of 2 to 4; percentage coarser than set averages 54, with a range from 36 to 86; and the percentage finer than half-set averages 16, with a range from 6 to 22. Figs. 42 and 43 are generalized from available screen tests.

Reduction ratio possible (ratio gape : set) in cone-type crushers is enormous as compared with other gradual-pressure type crushers. It results from the relatively great length of crushing face, and from the annular corrugation of crushing faces near the receiving opening, which has the effect of decreasing nip angle at a point where the apparent nip angle is too great for seizure. Despite the fact that the limiting size of product is about twice the closed setting, it is seen by reference to Table 20 that limiting-size reduction ratios of 6 or 7 to 1 are possible with most sizes of machine, although ratios of 3 to 5 are more common.

Capacity of the standard cone-type crusher in terms of reduction tons per hr. per ton weight of machine is nearly 3 times that of the standard Blake crusher, more than twice that of the standard gyratory, and nearly twice that of the reduction gyratory. Its performance record as to lost time for mechanical reasons demonstrates that it has the ruggedness to support the loading that it is rated for. The high capacity is to be attributed largely to the relatively great throw, while the small relative weight follows from the efficient overload relief afforded by the spring-backed bowl. Performance data, which are available in considerable number for the standard machines, indicate that except for the largest machines, users do not load to a point anywhere near maximum capacity. On the other hand, the reported performances of large cones with coarse bowls exceed the makers' ratings somewhat, and, since these ratings are reasonably consistent from size to size in the proportionality of capacity to discharge area and to throw, the indication is that they are conservative throughout.

The short-head capacity in reduction tons per hr. per ton weight of machine is only about 30% that of the standard machine. It is least, as might be expected, with fine bowls and tends also to fall somewhat with smallest settings.

Power consumption for 20 standard cones, according to questionnaire reports, ranges from 29 to 90% of installed, averaging 60%; for short-heads, the range is 55 to 96%, average of 11 is 75%.

Efficiency, according to the manufacturer, ranges, for the standard machine, from an average of 3.8 to 16.6 reduction tons per hp-hr., increasing regularly with size of machine. Performances are lower in the smaller machines, ranging from 1.8 to 18.7 reduction tons per hp-hr. for machines smaller than the 7-ft. size and averaging 6.9 for 14 mills reporting. The 7-ft. standard-machine performances range from 9.6 to 89.3 reduction tons per hp-hr., averaging 52.6 for 8 machines reported, against 16.6 average for the manufacturers' estimates. It is probable, however, that several of the figures estimated from performance reports are too high and that 25 reduction tons per hp-hr. is nearer a correct average. Short-head machines are much less efficient. The manufacturers' estimates range from 1.5 reduction tons per hp-hr. for the 3-ft. machine to 5.0 for the 7-ft. machine. Performances range from 1.5 to 7.5 reduction tons per hp-hr. Excluding the high and low figures, the average is 2.1.

Disk crusher is an obsolete machine which had considerable vogue from 1915 to 1925. Description and performance data may be found in *Ed. 1, 282–287*.

8. ROLLS

Rolls are of two general types—rigid rolls and spring rolls. RIGID ROLLS are the older type, rarely used at the present time because of their tendency to stall and to suffer mechanical damage. They differ from the type to be described in that the bearings for both rolls are rigidly fixed on the frame and the rolls must either stall or something must bend or break when an uncrushable particle or a rush of feed enters. They must be operated at low speeds to keep down bearing temperatures and machine breakage; consequently they have low capacities. Such rigid rolls as are now in use are ordinarily fitted with a breaking block or washer under the tension-bolt nut, which acts as a safety or break point.

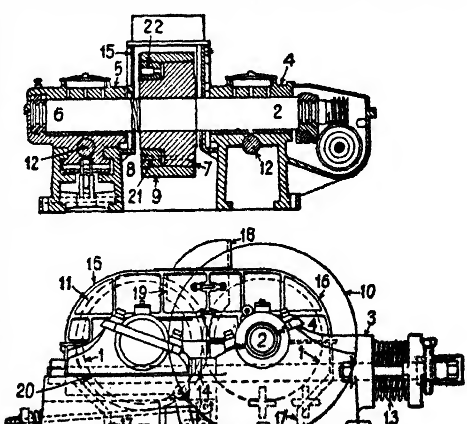

Fig. 44. Spring rolls.

Spring rolls are illustrated in Fig. 44. They consist essentially of two cylinders *1* mounted on horizontal shafts which are driven in opposite directions so that corresponding points on the cylinder faces above the horizontal plane through the shaft centers are moving toward each other. The main frame *3* carries the fixed bearings *4* and movable bearings *5*. These bearings carry shafts *2* and *6*. Near the centers of the shafts are the cores or hearts *7*, fixed, and *8*, removable, for holding the shells *9*. The fixed roll is driven by pulley *10* and the movable roll by a smaller pulley *11*. The movable roll is held up to

the fixed roll by means of two heavy tension rods *12*, carrying nuts that bear at one end against the movable-roll bearings and at the other end against a nest of springs *13*, which are seated against the main frame. The minimum distance between roll faces is fixed by the shims *14*. The rolls are encased in a housing consisting of fixed sides *15*, and covers *16* which are easily removed to permit inspection of the roll faces. Beneath the rolls a hopper *17* is provided to guide the discharge to a chute. A feed hopper *18* is bolted to the top of the housing. This hopper is fitted with replaceable distributing plates that spread the stream of feed out over the full width of the roll faces. Cheek plates *19* are provided to protect the housing from wear of the feed stream and to prevent material from passing between the sides of the rolls and the housing without crushing. Cheek plates, roll shells, and hopper liners are made replaceable. Replaceable steel strips *20* are provided to protect the frame from wear due to movement of the movable-roll bearing. Table 23 is generalized from catalogues of the principal makers and gives data as to sizes, weights, speed, and power consumption of rolls available without special design. There is a wide diversity in weight of a given size of roll as offered by different manufacturers. The lighter rolls should be chosen only for small capacities or very easy crushing or where first cost is of paramount importance; if they are used for heavy-duty free-crushing or for choke-crushing, lost time and maintenance costs are excessive. Heavy rolls for heavy service will repay the additional first cost in a short time in lower repair costs and continuity of operation.

a Suitable for the lower range of spring pressures and peripheral speeds below or around 1,000 f.p.m.
b Suitable for the heaviest service with high spring pressures and peripheral speeds of 2,000 f.p.m. or more.
c The selection gives the more usual sizes. Substantially double the number of widths are available at all diameters from 40- to 78-in. inclusive.

Frame is usually a one-piece casting with the lower half of the fixed bearing, the spring seat, and the discharge hopper cast integral; in large heavy-duty rolls, however, the frame is cast in longitudinal halves with heavy flanges and these are bolted together with fitted bolts. The sides of all but the smallest rolls are of box section, thus forming heavy box girders along both sides of the rolls under the bearings. The tops of the sides are machined at one end to form slides for the movable bearings and are fitted with removable steel wearing plates that protect them from the wear of the movable bearing. Cast iron, cast steel, or high-test iron is the usual material for frames. The bottoms of the frames of the better rolls are planed in order to give a smooth bearing on the foundation. In the better rolls heavy bosses are cast on the frame for the anchor-bolt holes; a sufficient number of these holes, of large enough diameter, should be provided to insure against serious vibration and shearing of bolts. The experience of a reliable manufacturer is the best guide available on this score. Recently some manufacturers have built frames of rolled-steel shapes and plates, riveted or welded. Such frames lack rigidity and are unsuitable for other than the lightest service.

Bearings are made extra long and heavy in order to distribute the heavy forces brought upon them. Normally they are split along planes at an angle of 20° to 30° to the horizontal as shown in Fig. 44. This is done in order to prevent shearing stresses on the bearing-cap bolts by bringing these bolts into lines substantially parallel to the direction of the resultant of the forces exerted in the bearings by the roll shafts. Movable bearings are mounted on a pedestal with a long base which is so fitted on a slide as to help assure keeping the movable roll in close alignment with the fixed roll. The slide is faced with a suitable wearing plate. Bearings are self-aligning, allowing the rolls to swivel in order to permit a hard object to go through on one side without bending the roll shafts. Babbitt or phosphor bronze is used for lining bearings, some users preferring one and some the other. In smaller rolls babbitted bearings are plain babbitted, in large rolls babbitted bushings are used in the lower half. With this provision the bearings can be rebabbitted by lifting the shafts but a small distance and slipping the bushings in under them. Some manufacturers provide a holding-down device for the movable bearing that prevents chattering and decreases wear on slides and bearings. Bearing caps are fitted with large reservoirs for grease or oiled waste, and generous oil passages should be cut in the babbitt to allow ready circulation to all parts of the bearing. Antifriction bearings have been used on light-duty rolls, but have not yet been tried for heavy duty. Some sort of dust cap should be provided over the bearing ends.

Tension rods are made of best forged steel or of alloy steel, of ample cross-section. One end is fitted with a heavy hexagonal nut with provision for pinning in position. The other end is threaded with a special thread for transmitting power and is fitted with a special nut or a gear wheel that works against the spring cage. Tension rods are placed as near the shafts as possible in order to bring them close to the line of the forces resisting crushing. One, two, or four are used each side according to the size of roll and type of duty. Single rods are placed below and multiple rods both above and below the roll shafts.

Springs are of the helical type and are carried in cast-steel cages; they are set to the proper tension at the factory. Working pressures range from 500 to 50,000 lb. per lineal in. of roll face, which correspond to spring pressures of about 1,500 to 30,000 lb. per spring. With the high pressures the rolls are practically rigid and, while there is enough give when an unbreakable article passes through to save bent shafts and broken frames in most cases, there is no doubt that there are more cracked frames with high spring pressures than with low. In free-crushing (see p. 73) the springs do not give until a pressure well in excess of ordinary resistance to crushing is exceeded. They take no part, therefore, in such crushing. With choke-feeding the rolls are spread against the spring pressure during the crushing and much of the crushing force is applied by the springs, which must, therefore, be kept under high pressure, if high effectiveness is desired. Two or four heavy bolts are provided for each cage. These bolts need not be disturbed when spacing the shells nor at any other time except in the event of replacing a broken cage or spring or when it is desired to change the spring pressure. Increase in spring pressure should be made with caution, as it is usually set by the maker as high as is safe.

Shafts are made of forged or alloy steel turned, polished, and keyed for pulleys. They should be heat-treated to relieve forging strain. In some makes of rolls the shafts are interchangeable and reversible; in other makes the ends are grooved for thrust collars and fitted for lateral adjusting devices in such a way as to prohibit the interchangeable feature. Normally, the diameter of the shaft is greater in the core than elsewhere, in order to put the most metal at the place of greatest strain. All dimensions should be generous, as the loads are tremendous and unpredictable.

Drive. Older practice was by pulleys and flat belts from a countershaft. The pulley on the fixed-roll shaft was large enough to transmit all of the power necessary for crushing; the smaller pulley on the movable roll, driven by a crossed belt, was designed to keep the roll moving when the machine was idling, so that there would be no lag to pick up when feed started again. Such rolls are rated RIGHT- or LEFT-HAND according to whether the large pulley is at the observer's right or left as he faces the end of the rolls carrying the spring cages. Most modern large rolls are fitted with Tex-rope sheaves, flywheel type, of the same diameter on both rolls, and are individually driven from separate motors. This arrangement is more compact and mechanically more efficient than the flat-belt drive. Light smooth-faced pulleys are made of wood, cast iron, cast semi-steel, or with steel disk and cast-iron or cast-steel rim. Cast pulleys are made with a split hub key-seated and with solid rim. In all cases the pulleys are balanced as perfectly as possible. Wood pulleys or steel-disk pulleys are recommended for vibrating duty such as is encountered in coarse crushing.

Usually pulleys are placed on opposite sides of the frame, but occasionally both pulleys are placed on the same side, the stationary shaft furnished with an outboard bearing. This arrangement is much superior from the standpoint of safety and convenience. Some slow-speed rolls (CORNISH ROLLS, p. 72; see also Sec. 2, Fig. 109) are gear-driven, as are also the toothed rolls used in coal breaking.

Roll centers, cores, or hearts are made of cast iron or semi-steel. A typical form for large rolls is shown in Fig. 44. The fixed heart 7 has a long tapered hub. It is pressed onto the shaft under hydrau-

lic pressure running up to 300 tons per sq. in. The movable heart *8* is split and drawn onto the hub of the fixed heart by bolts *21*. The outer surface of the hearts is tapered toward a least diameter along a circumference at the central transverse plane of the roll shell when in place. The roll shell is correspondingly tapered inside. Shells are put on by first removing the movable heart and slipping the shell over the fixed heart, then drawing the movable heart tightly in place by means of bolts *21*. Frequently the shell is expanded by heating at the time the cores are drawn together so that when cool it shrinks down on the cores. Gas and electrical-induction heaters are used. With the latter type it required (*54 CMJ 428*) 12 hr. to heat up and 15 min. to place on the core; cost of current was $1.70 with power at $25 per hp-yr. A special bolt *22* is provided for backing away the movable heart when necessary. One maker puts the taper on the shaft and makes the outer surface of the hearts and the inner surface of the roll shells cylindrical. The ADVANTAGES claimed for this method of construction are strengthening of the shaft at the point of maximum strain and greater ease in rolling the shells. A serious disadvantage lies in the fact that the expensive shaft is subjected to a possibility of considerable wear with resulting necessity for replacement.

Shells are made of high-carbon steel rolled similarly to locomotive tires, or of forged chrome steel rolled or bored to size and taper, or of manganese steel cast and ground to proper shape. In old practice the shells were made of chilled iron, but, on account of the impossibility of making a uniformly hard shell, this material pits rapidly and badly with resultant loss in crushing efficiency For light service, rolled high-carbon steel shells are entirely satisfactory. An advantage claimed for them is that, owing to the fact that the surfaces are not extremely hard, there is less failure to nip than is encountered with harder shells. Likewise they do not crack readily and therefore can be worn down very thin before replacing.

There is great difference in steels from various sources. The products of local or little-known shops are particularly to be regarded with skepticism. A typical analysis of a good rolled-steel tire is: C, 0.70 to 0.80%; Si, 0.12 to 0.25%; S + P, 0.05% maximum; Mn, 0.65 to 0.85%; Cr, 0.75% maximum. Proper heat treatment is of first importance. Manganese-steel shells have longer life on coarse feed than rolled steel, but on fine feed there is much less difference unless the feed is very hard and abrasive, or a high reduction ratio is attempted. Price of rolled-steel shells (1939) is 12 1/2 to 15¢ per lb.; manganese-steel shells cost the same or slightly more; the price of chrome-alloy shells may run up to 30¢ per lb.

Thickness of new shells ranges normally between 3 and 6 in., but in some modern heavy-duty rolls shells are 9 in. thick. Thickness at discard ranges in general from 1/2-in. for small rolls to 2 1/2-in. on large, the average being between 3/4- and 1-in.

Wear of roll shells is due to abrasion resulting from slipping of the faces past the rock particles and to gouging by hard particles; abrasion normally predominates. Slipping occurs in bringing rock particles up to shell speed, and when nip failure occurs the particles ride for a time in the vee until either they are abraded to nippable size or some undersize feed sands the track. Wear in the form of circumferential troughs (CORRUGATION) is common in free-crushing of coarse feeds, especially if the rolls are working with large nip angles. Corrugation causes loss of capacity and increase in circulating load. Remedies are various. The best is to correct feed conditions either by decreasing the working nip angle (see p. 65) or by changes in those respects in which the operation departs from the optimum conditions. Decrease in speed frequently improves nip. Lateral shifting of one roll, best done at regular short intervals, *e.g.*, 24 hr., decreases but will not prevent corrugation. Some mills set emery bricks so that they are continuously against the shells under constant pressure. At VAN ROI mill (*101 J 465*) the use of such bricks tripled the life of fine-roll shells. In SOUTHEASTERN MISSOURI flanged shells are taken off and ground or turned down in a lathe, according to whether they are manganese or rolled steel. A 54×20-in. high-carbon steel shell can be turned down in 20 to 30 hr., dependent upon the extent of corrugation (*57 A 346*). Manganese steel corrugates less than rolled steel, but is difficult and expensive to grind down after corrugation starts; one week to grind back is reported (*53 CMJ 66*). For rolls with wide faces the shells have been made in two rings. At OHIO COPPER CO. (*99 J 748*) shells for 60×24-in. rolls were in two sections, one 10-in. width and the other 14-in., but this construction induced grooving at the joint. Shells already circumferentially corrugated were transversely corrugated to the same depth on 2-in. centers and put back into operation; the effect reported (*53 CMJ 66*) was to wear the resulting bumps down and thus tend to level off to the bottom of the old corrugations.

In a mill where rolls are used for crushing different sizes of material, partly worn shells from fine rolls may be transferred to the coarse rolls, provided these are of the same size, since the loss of efficiency in coarse rolls, due to slight pitting, is much less than in fine rolls. Corrugation other than that due to incorrect distribution of feed is substantially absent in choke-crushing.

Life of shells under varying conditions of service is given in Table 24. Consumption ranges, according to rock, to shell material and to method of crushing, from 0.01 to 0.1 lb. per ton crushed for chrome-alloy and for manganese steels and from 0.04 to 0.15 for high-carbon steels. Consumption in choke-crushing is less than in free-crushing. At BRITANNIA BEACH (*139 #7 J 34; IC 6619*) shells for a 54-in. roll, cast at a local foundry (0.5 to 0.65% C, 0.70 Mn, 0.6% Cr), 7 in. thick, were worn to 1-in. thickness before discard; consumption was 0.19 lb. per ton of new feed when operating in closed circuit with a 3/16-in. screen, taking about 50 tons new feed per hr.

Time for changing shells is largely dependent upon the mechanical equipment available and the method of operation. Shrunk-on shells take longer to remove and to replace than those that are set cold. Most mills allow one shift for a change (see Table 24). It is common practice to keep newly shod shafts set up on crane-served blocks, in which case a change can be effected in 4 to 6 hr., much of the time lost being consumed in dismantling the feed chute and service platform.

Housing is made of cast iron or sheet steel. In most cases the lower part is cast integral with the frame and provided with a flange for bolting on the upper part. Most makers provide the upper part with cast-iron ribbed sides and sheet-steel cover. Hinged inspection doors of sheet steel or of canvas

ribbed with steel straps are provided over both rolls. The housing is made as nearly dustproof as is practicable. The shaft openings are covered with special devices to prevent emission of dust and grit. The sides of the housing are made sufficiently strong and stiff to carry the weight of the feed hopper and in some cases also to carry a feeder.

Cheek plates are made of hard iron or, rarely, of special steel. They are bolted to the inside of the housing in the hopper-shaped opening formed by the sides of the housing and the upper surfaces of the rolls. They should be made capable of lateral adjustment by means of bolts projecting through the housing so that they can be properly crowded up against the edges of the rolls to prevent the passage of uncrushed material between the sides of the rolls and the housing. Life of cheek plates is given in Table 24.

Feed hopper is placed to one side of the opening between the rolls in order to deliver the stream as nearly as possible to the center of the opening. It should be furnished with distributing plates for spreading the stream of feed across the full width of the roll faces. Adjustable side plates are also a convenience. Liner plates for the hopper are made of hard iron or manganese steel. The life of liner plates is from 30 days to several years. Commonly they are changed with the cheek plates.

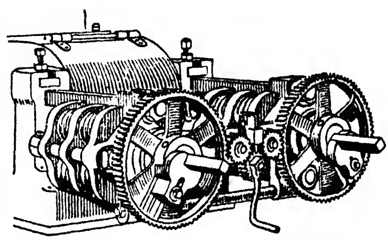

Fig. 45. End adjustment for setting rolls.

Lubrication of the main bearings in small rolls is best effected with grease, the consistency being varied with the temperature. Large rolls are usually lubricated with oil; in such case they should be fitted with an efficient circulating and filtering system, and the bearing ends must be covered with oil- and dustproof caps. Lubricant consumption ranges from about 2 to 50 lb. per 24 hr. according to the size of rolls, the kind of lubricant, and the efficiency and care in use.

Manufacturers. Allis-Chalmers Mfg. Co., Austin-Western Road Mach. Co., Birdsboro Steel Fdy. & Mach. Co., Chalmers & Williams, Colorado Iron Wks. Co., Denver Equipment Co., Eastern Iron & Mach. Co., Sturtevant Mill Co., Taylor-Wharton Iron & Steel Co., Traylor Eng. & Mfg. Co., United Iron Wks. Co., Vulcan Iron Wks., Webb Corp.

Adjustments possible in well-designed rolls are (*a*) the distance between roll faces and (*b*) lateral adjustment of one or both roll shafts. Adjustment of the distance between faces, or ROLL SETTING, is accomplished by changing the distance between the faces of the nuts at the two ends of the tension rods and by change of the total thickness of the shims placed between the forward end of the movable bearing and the frame. In making this adjustment it is important that the shafts be kept parallel. In most rolls this is accomplished by pinning the nuts at one end of the tension rods and so arranging the nuts at the other end that they are both moved equally and dependently by the adjusting mechanism. Fig. 45 illustrates the adjusting mechanism on one make of rolls in which the adjusting nuts are turned by spur gears operated by intermediate gears from a common pinion. This mechanism draws the movable-roll bearing up against a block of shims whose total thickness is that necessary to keep the roll faces a predetermined distance apart. As roll shells wear down, the shims are changed to allow the roll shafts to be drawn closer together and thus compensate for wear. This end-adjustment mechanism provides for backing the movable roll away from the fixed roll in order to free the rolls in case of clogging. It also allows the rolls to be backed away from or drawn up to the shims while running under load.

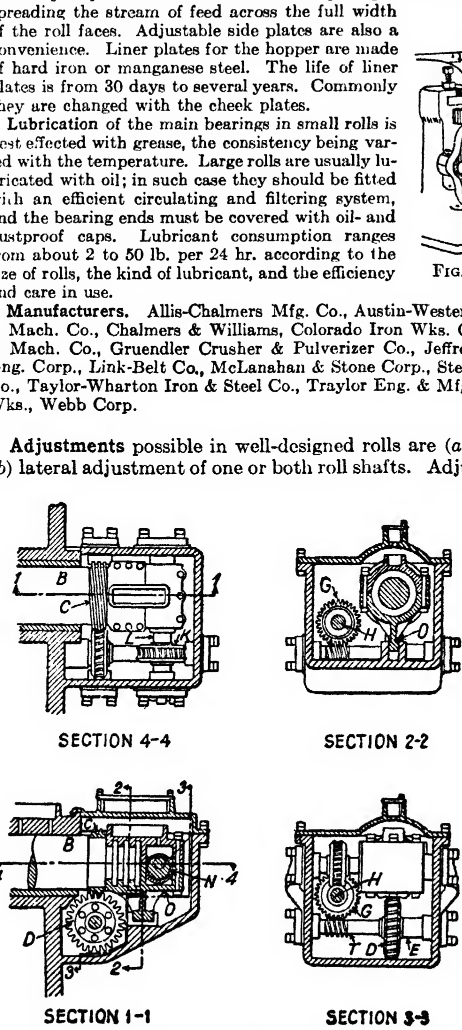

Fig. 46. Traylor automatic lateral adjustment for rolls.

r Core shrunk on shaft.
s Welded to side.
t Air hoist.
u One man to 2 gyratories, rolls, and vibrating screens.
v Hard-faced after 6 wk.
w 6 rolls and 6 ball mills per man.
x Changing shell.
y Carborundum bricks.
z Across-the-line starter.
aa Hard-faced as needed.
ab One attendant to entire fine-crushing plant.
ac Machine too light; much choking, adjustment, and repair.
ad Very hard siliceous ore.
ae One man part time for 2 rolls.
af One man handles 2 rolls, 2 screens, and 1 rotary drier.

Side adjustment is necessary to prevent flanging and circumferential corrugation. To prevent flanging, the range of side adjustment must be such that either edge of both rolls can be made to run for a part of the time, at least, on the face of the other roll. To prevent corrugation, rolls should be shifted through a distance of about 0.6 times the diameter of the largest particles in the feed. Lateral adjustment is accomplished manually or automatically. At SILVER KING COALITION (*99 J 615*) the life of shells on fine-crushing rolls was increased from 90 da. to 2 yr. by installing rolls with manual fleet and adjusting every 16 hr. The objection to manual adjustment is that it is likely to be forgotten or purposely neglected by the roll operator and that a short period of neglect may result in ruining the surface of a pair of shells. The only objection to automatic lateral shifting lies in the difficulty of making a simple, durable, and certain shifting mechanism.

Several operators have reported satisfactory performance of the Traylor mechanism shown in Fig. 46, but its use is limited. In this device the worm C cut on one end of the fixed-roll shaft B operates the worm wheel D on the transverse shaft E, set below the main shaft. The worm T on shaft E in turn drives the worm wheel G on shaft H. A worm on the other end of shaft H drives the worm wheel K on shaft L. Shaft L carries an eccentric sleeve N, fitted to a slide in a machined recess in the thrust collar O. This collar carries grooves into which fit corresponding collars cut on the end of shaft B. Lateral motion of the eccentric sleeve N is thereby transmitted to the shaft B which is caused to move backward and forward along the line of its axis through a distance determined by the throw of the eccentric N. This mechanism is enclosed in a dustproof case cast integral with one side of the roll frame. The case carries bearings for the various shafts. Variation in amount of lateral movement, or FLEET, is accomplished by changing the eccentric shaft L. The chain of gears is such that one complete cycle of roll-shaft movement is completed in about 30 min.

Sectionalizing. Most makers will furnish rolls up to 30-in. diameter sectionalized so that the heaviest piece does not exceed 300 or 350 lb.

Requirements for ideal rolls are that they should be rugged, simple in construction, and compact, and the working parts should be readily accessible; worn parts should be capable of easy change with as little dismantling of the apparatus as possible. Springs should exert a pressure sufficient to crush the hardest rock and yet should be sufficiently flexible to pass unbreakable substances without bending the shafts or breaking the castings. A substantially dustproof housing and large dust- and gritproof, well-lubricated bearings should be provided. The mechanism for adjustment for distance between roll faces should be capable of rapid and easy operation, in order to facilitate clearing the rolls in case of clogging, it should not necessitate a change in spring pressure, and it should advance both sides simultaneously in order to maintain proper alignment of shafts. If possible there should be automatic lateral adjustment of one of the roll shafts. Fleeting devices, however, add considerably to the first cost, and thorough investigation of their trustworthiness should be made before purchase.

Performances at a number of mills are shown in Table 24.

Angle of nip n is the angle formed by the tangents to the roll faces at the points of contact therewith of particles to be crushed. This angle is shown as angle ACB, Fig. 47, *a*. Particle P, which is to be crushed, is assumed to be spherical. If r is the radius and D the diameter of the rolls, d the diameter of particle, and s the distance apart of roll faces along the line joining the centers of the rolls, the following relation holds:

$$\cos\frac{n}{2} = \frac{r + s/2}{r + d/2} = \frac{D + s}{D + d}$$

Neglecting gravity, the particle is acted upon by forces applied at the points of contact in directions indicated by the lines F (Fig. 47, *b*). These forces can be resolved (considering one side only) into a normal force N and tangential force T. If the normal and tangential forces are resolved into their horizontal and vertical components respectively, it will be seen that the particle will be drawn down when the vertical component of T, acting downward, exceeds the vertical component of N, acting upward. The limiting condition is reached when the vertical components of T and N are equal but opposite in direction. Under this condition the particle will neither be nipped nor thrown out of the rolls but will ride in the hopper formed by the converging faces. With this condition the following equations may be written: $N_v/N = \sin n/2$; $T_v/T = \cos n/2$. Dividing the first equation by the second, $\tan n/2 = TN_v/NT_v$. But under the assumption $T_v = N_v$. Therefore $\tan n/2 = T/N$. From the ordinary relations of mechanics T/N = tangent of the angle of friction. For stone on iron the coefficient of friction (= tangent of the angle of friction) is about 0.3. Substituting this value in the above equation, $\tan n/2 = 0.3$; $n/2 = 16° 42'$, and $n = 33° 24'$.

In practice the nip angle rarely exceeds 25°. The average nip angle in 56 sets of rolls reported from the mills was 12° 44′ and the median was 12° 0′. The range in angle was

from 4° 40′ to 27° 4′. The angle averaged 19° 54′ for >2-in. feeds, 14° 28′ for feeds between 1- and 2-in., 11° 12′ for feeds between 0.5- and 1-in., and 9° 20′ for feeds smaller than 0.5-in. The averages for the coarser sizes are smaller, however, on account of the use of large rolls to get capacity. The larger angles used with coarse feeds (mills 25, 26, and 44) may be taken as a safe maximum figure.

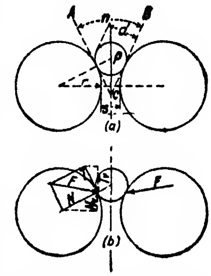

Fig. 47. Nip angle of rolls.

Since angle of nip decreases with increase in roll diameter, increase in set, and with decrease in size of feed particle, it follows that large rolls must be used for coarse feeds unless a small ratio of $d : s$ is acceptable.

Failure to nip, if not gross, can always be overcome by transverse corrugation of the shell at one or more places, but such expedients introduce a periodic shock in operation which tends to cause vibration and flapping drive belts, and also accelerates roll wear and aggravates breakage of shells. Slight slipping of scalped feed in free-crushing can be corrected by diverting a small amount of undersize to the feed, *e.g.*, by placing a longitudinal blank strip on a vibrating feed screen; the principle is that of sanding the track; actually the small particles in the vee between roll face and large sliding particle serve to reduce the nip angle over the areas at which they make common contact. At Hartland-Verona Gravel Co. (*42 #1 RP 38*), failure to nip was decreased by stepping the roll faces to produce the same effect as in the bowl of the standard cone crusher (Fig. 39); steel consumption was, at the same time, materially reduced.

Diameter of rolls required for various sizes of feed at different nominal maximum reduction ratios may be determined by Eq. 12, which is obtained by substituting the value for cos 12 1/2° in Eq. 11 and making the obvious transformation and approximation.

$$D = 40(t - s) = \frac{40d}{F_s}\left(1 - \frac{1}{R_w}\right) \tag{12}$$

where d = limiting size of feed and t is thickness of the thickest feed particle (presumably also the largest). The corresponding square-mesh limiting screen is tF_s. By rearrangement of Eq. 12

$$t = s + D/40 \tag{13}$$

which is the basis for the manufacturers' tables giving the largest recommended feed for various roll diameters. Conversely, the NOMINAL MAXIMUM REDUCTION RATIO (R_N) possible with rolls of a given diameter and setting may be derived from the equation

$$R_N = (40s + D)/40s \tag{13a}$$

for a 25° nip angle.

In practice coarse-crushing rolls (feeds coarser than 1-in.) are rarely less than 60-in. diameter; rolls for crushing intermediate sizes (1-in. to 1/2-in.) range from 36-in. to 78-in. according to capacity demands; for fine feeds the usual diameters are 36 or 42 in., with larger diameters used for heavy duty; use of rolls less than 36-in. diameter is unusual in metalliferous-ore concentrators.

Reduction ratios. The limiting ratio (Eq. 1) is the one usually stated; it ranges (Table 24) from 1.0 to 2.0 for light-duty rolls in the gravity-concentration mills cracking down slowly in order to minimize slime production, and for heavier-duty rolls in coarse intermediate service; it is from 2 to 4 for the average run of heavy-duty choke-crushing service; and runs up to 15 to 20 in very heavy duty choke-crushing with high circulating loads when making 10-m. ball-mill feeds. Working ratios (Eq. 3) average 1 1/2 to 2 times the limiting ratios in light-duty rolls running, in general, with light spring pressures; the failure of the limiting ratio to follow arises from the spreading of the rolls when choke-crushing conditions occur. Working ratio and limiting ratio are substantially the same in heavy-duty service; in extra heavy service, typified by Utah and Alaska-Gastineau, the excess of the limiting ratio is due to interparticle crushing and grinding incident upon maintenance of a substantially continuous ribbon several particles thick, subjected to heavy spring pressure. The nominal maximum ratio (Eq. 13*a*), when compared with the working ratio, is a useful criterion of the reliability of the data, or of the assumptions made in working them up; if the working ratio exceeds the nominal maximum, the implication is that the rolls are working above the allowable nip angle, and when the calculation has involved a preceding calculation of mean spacing in rolls set close (Table 24, line 2), the result of this calculation is brought into question. The excess in working ratio shown in Table 24, Column 26, is due to the fact that the nominal maximum ratio is based on an allowable nip angle of 25°, while the data indicate that this roll is working at 27°. High nominal maximum ratios correlate in general with close settings and/or large-diameter rolls. The 80% ratio (Eq. 5) is used primarily for calculation of capacity; an excess of this value over the limiting ratio is normal owing to the great concaving effect that a small amount of tramp oversize has on the cumulative sizing curves for fine materials.

The striking thing to be learned from Table 24 is that except in fine-crushing service, operating with choke-feed and high circulating load, the size reduction effected by rolls is ridiculously small. They do, however, effect cracking to two-thirds to half-size with the production of a very small amount of fines (see Table 24*a*).

Speed of rolls is limited by the ability to nip and by the weight and ruggedness of the rolls. Hence the allowable speed is affected by the diameter of rolls, the kind of ore, method of feed, reduction ratio, and size of feed. Speed should be lower for hard, tough rock than for soft and brittle rock, less for dry feed than for wet feed, less for coarse feed than for fine, and less for a large reduction ratio than for a small, nip being the controlling factor in each case. The speeds reported range from 440 f.p.m. for rolls 30-in. diameter, to 3,220 f.p.m. for rolls 78-in. diameter. Practice tends to keep below 1,000 f.p.m. with rolls up to 36-in. diameter, below 1,500 f.p.m. for rolls up to 60-in. and not to exceed 2,500 f.p.m. with larger machines, more or less independently of other factors, since higher speeds are dangerous to springs, shafts, frames, and foundations. On the other hand, the MIAMI operation at upward of 3,200 f.p.m. with a 78-in. roll is reported (*PC*) to be quieter than at lower speeds. With choke feeding, rolls of large diameters, flywheel pulleys, and general extra heavy construction, some authorities recommend speeds up to 2,000 f.p.m. for 36-in. diameter, 2,400 f.p.m. for 48-in., and 3,000 upward for 60- to 90-in.

At MIAMI COPPER Co. 55-in. rolls taking <3.5-in. feed were run at 100 r.p.m. and the same size roll taking <2-in. feed run at 115 r.p.m. At ENGELS (*123 P 183*), crushing to 1-in. in 54×24-in. rolls, capacity was increased and power decreased 40% by a decrease in speed from 110 to 54 r.p.m. because of improvement in nip. At CONSOLIDATED M. & S. Co. (*61 CMJ 496*), increase in peripheral speed of 74-in. rolls, from 1,000 to 1,330 f.p.m. permitted closing circuit and return of 150% circulating load without reduction in tonnage; operation was quieter than in open circuit and product finer.

Cornish rolls, gear-driven at 50 to 100 f.p.m. peripheral speeds, are occasionally met. The allowable nip angle is much greater at these low speeds and the product is likely to contain more fines than the product of high-speed rolls because of the tendency toward choke-feeding and restriction of discharge.

Capacity of rolls. The theoretical capacity in tons per hr. is given by the equation

$$C = NDWs\delta/293 \qquad \textbf{(14)}$$

where N = r.p.m.; D = diameter of rolls, W = width of face, and s = set, all in inches; and δ = the specific gravity of the rock being crushed. The development of this equation is based on the assumption of a solid ribbon of crushed material with length equal to 60 times the distance traveled by a point on the roll face in one minute, width equal to the width of the roll faces, and thickness equal to the set of the rolls. With open setting and free-crushing the actual capacity never reaches the weight of the THEORETICAL RIBBON. The theoretical ribbon is more nearly approached the smaller the set.

Ribbon factor (r) is the ratio of actual tonnage passing through rolls to the tonnage of the theoretical solid-rock ribbon. Its value in percentage is given by the formula

$$r = 2900T_T/Psw \qquad \textbf{(15)}$$

in which T_T is the hourly total of new and circulating feed tonnage, P is peripheral speed in f.p.m., s = set in inches, and w = width of roll face in inches.

The ribbon factor varies according to the set of the rolls and the degree of loading. Ranges and average figures from practice (Table 24) are as follows: 1 1/2-in. set, 1.4 to 4.8, aver. 2.6; 5/8- to 7/8-in. set, 2.4 to 30, aver. 10; 3/8- to 1/2-in. set, 2 to 37, aver. 18; 3/16- to 5/16-in. set, range 6 to 146, aver. 31; 1/10- to 1/8-in. set, 55 to 469, aver. 155; 1/16-in. set, 32 to 470, aver. 148; 1/40-in. set, 51 to 325, aver. 148. The high end of the range for all sets finer than 3/8-in. corresponds to choke-crushing with large circulating loads returned by a circuit-closing screen.
